cells is itself not sufficient for recommending allogeneic HCT, as abnormal cytogenetic clones have been transient in some cases. However, if repeat marrow examination reveals clonal evolution (i.e., the development of cytogenetic abnormalities in addition to the original abnormality) or clear progression in the proportion of cytogenetically abnormal cells, transplant should then be considered. In most cases, such clonal progression occurs with worsening cytopenia or progressive dysplasia in multiple lineages.

Diagnosis

Due to considerable overlap of the FA phenotype with other genetic and non-genetic diseases, the diagnosis of FA is often difficult and unreliable on the basis of clinical manifestations alone. While FA should be strongly suspected in patients with phenotypic features consistent with FA, especially if there is concomitant macrocytosis or cytopenia, many patients with FA may not have any of the classical clinical manifestations. Schroeder et al. [23] first suggested the use of spontaneous chromosomal breakage as a cellular marker for FA, but longitudinal studies of chromosome instability in FA patients showed this finding to be inconsistent. In contrast, hypersensitivity of FA cells to the clastogenic (chromosome-breaking) effect of cross-linking agents provides a reliable cellular marker for the diagnosis of this disorder (Figure 76.5). Diepoxybutane (DEB) and mitomycin C (MMC) are the two agents most widely used to make the diagnosis of FA. Extensive experience with DEB and MMC testing has demonstrated the sensitivity, specificity, and reproducibility of the results [24,25]. Cross-linker hypersensitivity can be used to identify the preanemic patient as well as the patient with AA, MDS, or leukemia who may or may not have the physical stigmata associated with FA. It is recommended that all patients exhibiting any congenital malformation known to be associated with FA or diagnosed with aplastic anemia at any age, have a peripheral blood sample tested for cross-linker hypersensitivity [10]. Children with cancer, in particular MDS or acute myeloid leukemia, found to be peculiarly hypersensitive to chemotherapy, or young adults (age <40 years) diagnosed with epitheloid tumors of the head and neck might also be considered for FA testing. Importantly, *all full siblings of an FA patient should also be screened without exception*, recognizing that there is a lack of concordance of the FA phenotype among affected siblings.

Data from DEB testing indicate that there is great variability in the degree of hypersensitivity in FA patients, although there is no overlap with the normal range [24]. In approximately 25% of FA patients, DEB testing will reveal two populations of phytohemagglutan A (PHA)-stimulated peripheral blood lymphocytes; one demonstrating an FA phenotype with chromatid breaks and exchanges and the other a normal one [12,26]. While there is no obvious correlation between the degree of cross-linker hypersensitivity and a specific FA gene mutation, severity of the phenotype in FA patients or individual patient sensitivity to chemoradiotherapy (JE Wagner and AD Auerbach, unpublished data), there may be an increased risk of graft rejection after HCT in patients with a low mean number of breaks per cell after exposure to DEB. This finding, however, is related to the proportion of DEB-resistant cells rather than a difference in the cross-linker sensitivity [12,27]. Beyond the possible correlation between DEB-resistant PHA-stimulated T lymphocytes and graft failure after HCT, patients with marked skewing toward DEB-resistant cells may be misdiagnosed as not having FA. In an analysis of DEB results at Rockefeller University, 25% patients had 25% or more of their cells without chromosomal breaks on treatment with 0.1 ug/mL DEB and 2% had >90% of cells without chromosomal breaks. Despite a low mean number of breaks per cell (which in some cases may overlap with or approach the normal range), FA patients have >1 break/cell within the aberrant cell population not seen in non-FA patients [12]. However, under such circumstances, testing of skin fibroblasts is recommended. Still, even within these patients with a substantial proportion of DEB-resistant cells, it is critical that the diagnostic laboratory report not just the mean breaks per cell but also the number of breaks per aberrant cell.

Importantly, the clinician should know that the chromosomal breakage test can also be applied to the study of fetal cells obtained by chorionic villus sampling (CVS), amniocentesis, or percutaneous umbilical blood sampling. If the specific mutation is known within the family, testing for the presence of the mutation on limited quantities of uncultured cells is possible and rapid. Alternative diagnostic methods for FA, such as by cell-cycle analysis using flow cytometric methods on lymphocytes exposed to cross-linking agents, are sometimes used as a research tool. While it is clear that duration of the G2/M phase is increased in FA cells as compared to unaffected cells, clinical diagnostic laboratories do not often use this method. In contrast, the immunoblot assay of FANCD2 protein monoubiquitination is a rapid diagnostic test for FA. However, rare patients with mutations in FA genes downstream of FANCD2 (i.e., downstream factors discussed later) or patients with significant somatic mosaicism would be missed by this approach. Finally, it has been reported that measurement of serum alpha fetoprotein (AFP) levels may be a sensitive and reliable test for FA [28]. Of 63 FA patients evaluated between 2005 and 2011 at the University of Minnesota, 84.4% had elevated AFP levels (normal range varies by age but is 0–8 ug/L for children $\geq$6 years and adults) (R Mitchell, H Zierhut, and ML MacMillan, unpublished data). Whether AFP levels can differentiate FA subpopulations is unknown; however, six of six patients with biallelic mutations in FANCD1/BRCA2 gene have had particularly high AFP levels (range, 43.5–106.6 ug/L) well above most other FA patients. Together, these data suggest that AFP may provide supportive evidence for the diagnosis of FA in general; however, AFP does not replace the need for the standard chromosome breakage test.

Once a patient has been diagnosed with FA by cross-linker hypersensitivity, molecular genetic testing is recommended. For example, the specific gene affected may be associated with differences in time to marrow failure and length of survival (Figure 76.6). Knowing the FA gene defect can be important for reproductive counseling and carrier testing (see section on "Genetic counseling").

The FA pathway and DNA repair

FA or FA-like syndromes are caused by mutations in at least one of 17 distinct genes (Table 76.2). These FA genes act cooperatively to coordinate DNA repair, particularly interstrand cross-links. While there is no consensus on the precise nature of the FA pathway, models exist that explain network interactions between FA proteins and other repair networks, including the breast cancer (BRCA) susceptibility protein [29–35]. Disruption in the pathway, however, leads to dysregulation of the signaling pathways that guide cell proliferation and apoptosis as well as inefficient DNA repair, leading to the congenital malformations, hematopoietic failure, and cancer characteristic of FA.

The FA pathway is evolutionarily conserved and FA proteins interact with numerous DNA repair circuits to maintain genome stability. Functionally, the FA-BRCA pathway can be subdivided into three compartments: (1) a large multisubunit upstream core complex with E3 ubiquitin ligase activity, (2) two monoubiquinated central effector proteins, and (3) downstream factors (Figure 76.7). As a group, FA proteins interact with additional proteins to repair interstrand crosslinks, participating in homologous recombination and translesion synthesis, as well as processes that maintain genomic stability during DNA replication.

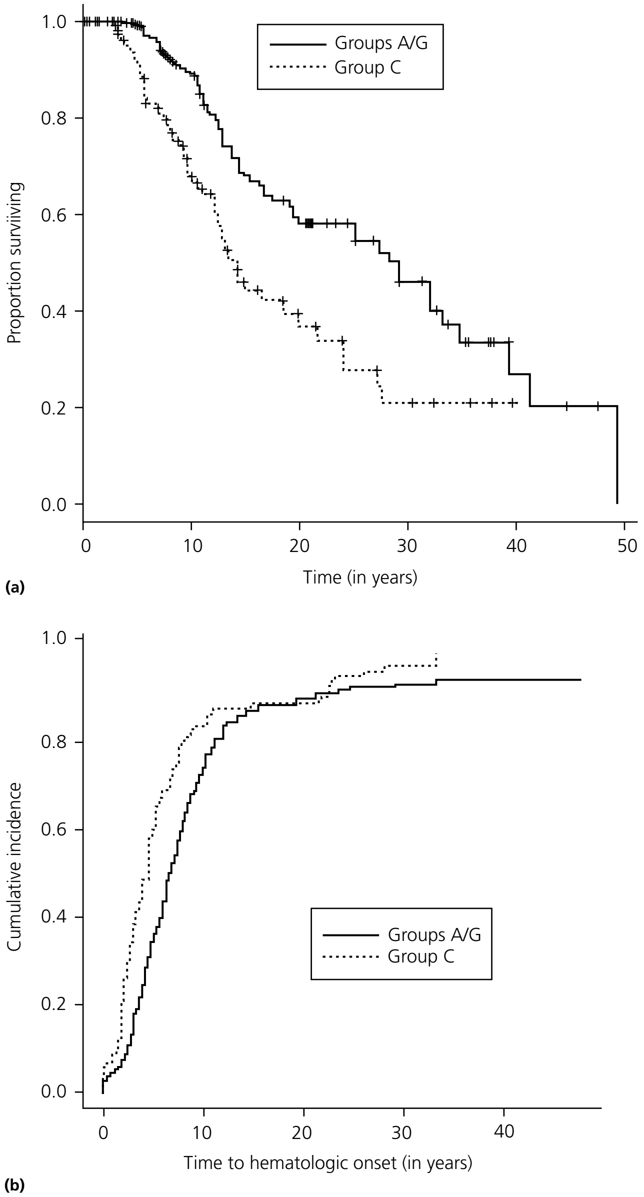

Figure 76.6 Survival and time to marrow failure was compared for FA patients in complementation groups A, G, and C. Survival and incidence of marrow failure was similar in groups A and G. Comparison of the combined groups A/G with group C showed that patients in group C had a significantly shorter survival (a) and higher incidence of bone marrow failure (b). Upstream core complex. The FA core complex proteins assemble in the nucleus and are necessary for monoubiquination of *FAND2* and *FANCI*, the central effectors in protection of genome integrity. Eight FA proteins (FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, and FANCM) and three FA associated proteins (FAAP100, FAAP24, and FAAP20) are members of the nuclear core complex. Importantly, three of these upstream core complex genes, *FANCA*, *FANCC*, and *FANCG* are responsible for nearly all cases of FA (62%, 15%, and 9%, respectively). Additional information regarding FA mutations can be obtained from the Fanconi Anemia Mutation Database at http://www.rockefeller.edu/fanconi/mutate/ (accessed February 4, 2015).

Table 76.2 The Fanconi anemia genes: description and frequency in the IFAR database

FA Group	FA Gene	MIM #	Location	Exons	Amino Acids	Frequency	Protein Function
Core Complex Factors							
A	*FANCA*	607139	16q24.3	43	1455	60%	Core complex member
B	*FANCB (FAAP95)*	300515	Xp22.31	10	859	2%	Core complex member

F	*FANCF*	603467	11p15	1	374	2%	Core complex member
G	*FANCG (XRCC9)*	602956	9p13	14	622	9%	Core complex member
L	*FANCL (PHF9/FAAP43)*	608111	2p16.1	14	375	0.5%1	Core complex member; E3 ubiquitin ligase
M	*FANCM (Hef/FAAP250)*	609644	14q21.3	22	2048	0%	Helicase, localizes the core complex to DNA
Central Factors/ID Complex							
D2	*FANCD2*	227645	3p25.3	44	1451	3%	Binds DNA structure, exonuclease activity
I	*FANCI (KIAA1794)*	609053	15q26.1	38	1268	1%	Aids in proper monoubiquination of FANCD2
Downstream Factors							
D1	*FANCD1 (BRCA2)*	605724	13q12.3	27	3481	3%	Binds ss and ds DNA; stimulates RAD51 strand exchange (HR mediator)
J	*FANCJ (BRIP1/BACH1)*	605882	17q22	20	1249	3%	Helicase that unwinds DNA with 3′-5′ polarity; interacts with BRCA1
N	*FANCN (PALB2)*	610832	16p12	13	1186	0.5%	Helicase, translocase; stabilizer of FANCD1
O	*FANCO (RAD51C)*	613390	17q22	9	376	0%	Binds ss DNA (HR mediator)
P	*FANCP (SLX4/BTBD12)*	613951	16p13.3	15	1834	0.2%	Scaffold for structure-specific nucleases (Holliday junction resolvase)
Q	*FANCQ (ERCC4/XPF)*	615272	16p13.12	11	916	0.1%	Associates with ERCC1 to form a FANCP/SLX4-dependent interstrand crosslink unhooking nuclease; participates in nucleotide excision repair
S	*FANCS (BRCA1)*	113705	17q21.31	22	1863	0.1%	HR; inhibition of non-homologous end joining

Of 1168 FA patients in the IFAR database, the complementation group assignment has been made for 790 North American IFAR patients.
*intron 4 is now intron 5 based on the RefSeq used for mutation nomenclature (see: http://chromium.liacs.nl/LOVD2/FANC/refseq/FANCC_codingDNA.html) (accessed March 6, 2015).

In addition to the monoubiquination of the FANCD2 and FANCI, the FA core complex may play additional roles. There is emerging evidence that FA core complex suppresses the activation state of intracellular effectors of apoptosis and to facilitate survival signaling pathways, including the JAK-dependent STAT activation pathway, thus promoting cell survival. For example, FANCC interacts with the molecular chaperone heat shock protein 70 (Hsp 70) to protect HSC from cytotoxicity and apoptosis on exposure to interferon gamma (IFN-γ) and tumor necrosis factor-alpha (TNF-α) [36]. Together these interactions protect cells from a variety of environmental factors, including oxidative stress and radiation, as well as suppress double-stranded RNA-dependent protein kinase activity and caspase 3 activation [37]. While there has been tremendous progress in our understanding of the FA proteins and their role in DNA repair, cell-cycle checkpoints, oxygen metabolism, and induction of apoptosis, there is much to be fully elucidated.

Central effectors. Following DNA damage (by DEB, MMC, and other DNA-damaging agents) and during S-phase of the cell cycle, FANCD2 and FANCI are monoubiquitinated by the FA core complex which contains FANCL, an E3 ubituitin ligase. FANCD2 and FANCI are also phosphorylated as a consequence of DNA damage by cell cycle checkpoint kinases, ataxia telangiectasia mutated (ATM) and ataxia telangiectasia and RAD3-related (ATR). While phosphorylation is critical for checkpoint signaling during S phase and for monoubiquination of FANCD2/FANCI (ID complex), the precise role for this DNA damage-dependent phosphorylation of multiple FA proteins is unclear [38–44]. The FA-ID complex associates with chromatin and forms the functional fulcrum of the FA pathway SLX4 (FANCP), a downstream FA protein, which is recruited to the site of damage, and a variety of FA-associated nucleases, including XPF-ERCC1, MUS81-EME1 and SLX1, and FAN-1 cooperate with other proteins to excise the intrastrand crosslink, induce double strand breaks and prime the broken DNA strands for repair [35,45–47]. Failure to monoubiquinate FANCD2, as is observed in FA individuals with biallelic loss-of-function mutations in nuclear core complex genes, also causes hypersensitivity to cross-linking agents and poor maintenance of genome stability. Presence of the monoubiquinated long forms of FANCD2 and FANCI, however, does not exclude FA as some patients have mutations downstream of the central effectors [48].

Downstream factors. After cross-link excision, the FANCN/PALB2, 5′-3′ helicase FANCJ/BRIP1, FANCD1/BRCA2, FANCO/RAD51C, FANCS/BRCA1, RAD51, and other proteins assemble at the 3′-flap of single strand DNA. This enables invasion of the remaining broken strand and repair by homologous recombination. More recently, FANCP/SLX4 was identified as a novel FA gene. FANCP/SLX4 acts as a docking platform for multiple structure-specific nucleases. FANCP/SLX4 binds to the XPF (ERCC4) and MUS81 subunits of the XPF-ERCC1 and MUS81-EME1 nucleases, critical to DNA interstrand cross-link repair. Because cells deficient in FANCP/SLX4 have normal monoubiquination of FANCD2, FANCP/SLX4 is classified as a downstream factor. As other downstream Fanconi anemia proteins (i.e., FANCD1/BRCA2, FANCS/BRCA1, FANCN/PALB2, and FANCJ/BRIP1) are breast cancer susceptibility genes, it is possible that mutations in FANCP/SLX4 may also be associated with breast cancer; recent studies support this claim [46,47].

Why this is significant to the transplant team? The disrupted FA pathway does not respond appropriately to DNA damage, resulting in the accumulation of damage during DNA replication and loss of genomic integrity. This may lead to apoptosis and consequently high risk of developmental defects during

Figure 76.7 Model of the FA pathway in DNA repair compiling the most recent data. (a) Step 1: DNA damage and stalled replication fork signal ATR results in phosphorylation of the FANCA, E and G of the core complex, and FANC D2 and I of the I-D complex, RAD51C and histone H2AX as well as activation of p21 which downregulates USP1 deubiquitination enzyme and in turn permits ubiquitination of FANC D2 and I. Step 2: Upon recognition of the intrastrand DNA cross-link (ICL), FANCM and FAAP24 and FANCM-associated histone fold 1/2 bind near the site of the intrastrand cross-link and recruit the 8-member core complex which assembles the core nuclear ubiquitin ligase complex which monoubiquinates FANCD2 and FANCI. (b) Step 3: The modified I-D protein complex associates with chromatin and recruits FAN1 critical to excision of the ICL and formation of 3′ flaps of ssDNA for repair. Step 4: Downstream proteins FANCN, D1, J, O and P, and BRCA1 assemble and nucleate the single strand DNA with RAD51C. Step 5: This enables homologous recombination and ICL/double-strand break (DSB) repair. Mutations any of the FANC genes leads to inability to repair ICL efficiently. Loss of the FA pathway leads to chromosomal aberrations upon exposure to cross-linking agents such as diepoxybutane (DEB), leading to an infrequency of chromosomal breaks and radial figures as shown in the side panel. Source: Courtesy of Betsey Hirsch PhD. Model based on a compilation of data [29–52]. (For a color version of this figure, please see the color plate section.)

embryogenesis and bone marrow failure over the first two decades of life, as well as a series of mutations and consequent marked predisposition to leukemia and solid tumors. This knowledge of the FA pathway also explains the marked sensitivity of FA patients to (a) chemoradiotherapy and the need for marked dose reductions of cross-linking agents, such as daunomycin, carboplatin, cyclophosphamide, irradiation in the treatment of leukemia and cancer, in contrast to antimetabolites, like fludarabine, cytarabine and methotrexate, or (b) the use of psoralens with ultraviolet A (PUVA) therapy for the treatment of mucocutaneous chronic graft-versus-host disease (GVHD). Because of the possibility of accumulated DNA damage in residual HSC of FA patients, any proposed trials of gene-corrected HSC come with substantial risk, particularly in older patients with FA. The malignant transformation of gene-corrected HSC would be particularly difficult to treat since the corrected cells will be relatively chemotherapy-resistant (compared to uncorrected cells), requiring higher dose therapy in patients who cannot tolerate high-dose therapy. In summary, an understanding of the FA pathway helps the practitioner understand the rationale for recommending minimizing exposure to ionizing and UV radiation (i.e., routine dental radiographs, importance of sunscreens), hypersensitivity of FA patients to chemoradiotherapy prior to transplant and treatment of leukemia and solid tumors and the importance of a complete family medical history, need for FA gene mutation analysis and potential consultation with a genetic counselor [i.e., particularly if downstream factor genes associated with cancer risk in the carriers (e.g., parents) are mutated].

Pathophysiology of marrow failure and leukemogenesis

Children and adults with FA have an extraordinary predisposition for the development of marrow failure and leukemia. At birth, the blood counts are typically normal. Overtime, the first sign of any hematologic abnormality is often an increase in mean corpuscular volume (MCV). While anemia is classically considered the hallmark of FA, any one or all three hematopoietic lineages may be affected at the time of initial presentation. Other hematologic abnormalities include elevated fetal hemoglobin, low frequency of CD34 cell counts by flow cytometry, and low colony-forming capacity even at the time of birth based on assessments of umbilical cord blood (UCB) from affected neonates. Based on the genomic instability inherent in all the tissues of affected individuals, but in particular rapidly dividing cells like those in the hematopoietic progenitors, progressive depletion of HSC and clonal expansion of mutated cells ultimately lead to marrow failure and leukemia in almost all.

In order to better understand the pathophysiology of bone marrow failure, a number of murine models have been developed. Knockout models exist for FA core complex (fanca, fancc, fancg, fancf, and fancm), ID complex (fancd2), and downstream factors (fancd1 and fancp) [53–67]. In fanca–/–, fancc–/– and fancg–/– mice, the blood counts are normal (except for mild thrombocytopenia in fanca–/– mice); however, marrow progenitors are hypersensitive to IFN-γ and TNF-α both in vitro and in vivo, and have reduced numbers of HSC and reduced competitive repopulation potential relative to normal controls [56]. Similarly, fancd2–/– mice and mice with a hypomorphic mutation in fancd1, also have a reduced frequency of HSC and engraftment capacity albeit more severe in the fancd1 hypomorph. While none of the murine models completely recapitulate the human FA phenotype, in particular, progressive marrow failure, all models demonstrate genomic instability, cell cycle defects and hypersensitivity to DNA cross-linking agents. As such, these models may be useful in further exploring hypotheses derived from observations in FA patients (and FA cells in vitro) and identifying cellular and environmental factors that may impact the pace of HSC depletion. For example, Wang et al. [68] studied the function of constitutively expressed normal human FANCC protein in mouse hematopoietic cells. HSC from FANCC over-expressing transgenic mice were resistant to the cytolytic effect of a *fas*-triggering antibody, suggesting the *fas*-mediated apoptosis is involved in the pathogenesis of marrow failure in FA. Antisense oligonucleotides complementary to FANCC messenger RNA (mRNA) inhibited the in vitro clonal growth of normal erythroid and granulocyte–macrophage progenitor cells, even in the presence of exogenous growth factors. In contrast, peripheral blood CD34$^+$ cells isolated from a FA-C patient and infected with *FANCC* cDNA exhibited a 5- to 10-fold increase in the number of progenitor colonies in vitro. These results suggest that the *FANCC* gene plays a direct role in the survival of hematopoietic progenitor cells [69–71]. Rathburn et al. [72] proposed that marrow failure in patients with FA results from the accumulated losses of HSC caused by repeated episodes of low IFN-γ released in response to recurrent minor inflammatory stimuli. The capacity of IFN-γ to induce TNF-α gene expression is increased in the serum of children with FA [73]. Whitney et al. [74] postulated that the apoptotic phenotype in hematopoietic stem and progenitor cells creates an environment for the selection of IFN-γ resistant clones. Their findings argue that therapies designed to correct the abnormal pattern of IFN-γ sensitivity in FA cells may prevent or delay the onset of marrow failure and development of MDS and leukemia. Briot et al. [75] also showed that activation of two major stress signaling pathways, the mitogen activated protein kinases (MAPK) and the NF-κB transcription factor, induces many cytokines, including TNF-α. Together these data provide strong rationales for new clinical trials designed to correct the abnormal pattern of IFN-γ sensitivity in FA cells or reduce the levels of TNF-α which could prevent or delay the onset of marrow failure and development of MDS and leukemia. Among the hypotheses to be tested, recent focus on the role of aldehydes is particularly noteworthy. Garaycoechea and Patel et al. [76] considered the possibility that reactive aldehydes might be a cellular source of DNA cross-linking agent that may deplete FA HSCs based on the observation that FA-deficient cell lines are hypersensitive to acetylaldehyde and formaldehyde in vitro. Interestingly, bone marrow failure occurred in FA mice that were also deficient in acetylaldehyde detoxifying enzyme ALDH2 (fancd2–/– aldh2–/–) upon exposure to ethanol, the metabolic precursor to acetaldehyde. Also of interest was the spontaneous development of acute leukemia in these mice.

Why this is significant to the transplant team? Understanding the pathophysiology of FA marrow failure and leukemogenesis could help us find ways to ameliorate the disease progression as well as explain certain clinical observations. For example, in children with FA, blood counts often plummet after viral illnesses, in particular varicella zoster and respiratory viruses, which will recover over a period of 2–4 weeks but rarely back to baseline. In vitro and in vivo data suggest that FA HSC are hypersensitive to IFN-γ and TNF-α, both explaining these clinical observations and underscoring the importance of preventing viral illnesses. The models may also be useful in the development of preventative strategies (i.e., limiting alcohol exposure and aldehyde-generating foods) and optimization of forthcoming treatments, such as gene-corrected autologous HSC where exogenous factors (e.g., IFN-γ) might be needed to give the corrected HSC a competitive growth advantage over uncorrected HSC.

Somatic mosaicism

Somatic mosaicism is the state when genetically distinct populations of somatic cells can be found within an organism. Mosaicism can be caused by DNA mutations, epigenetic alterations of DNA, chromosomal abnormalities, and the spontaneous reversion of inherited mutations. As in many other inherited disorders, somatic mosaicism has been found in FA [12]. In fact it is relatively common – up to 65% of FA patients will have a population of T lymphoblasts that is resistant to DEB. The question now is whether mosaicism occurs beyond the lymphoid lineage and whether it has any clinical significance specifically in patients with FA.

To date, several reports of genetic reversion in the HSC with longitudinal data suggest that such reversion may prevent marrow failure. In the first case, Gregory et al. [77] demonstrated somatic reversion in the HSC as evidenced by loss of the maternal *FANCA* mutation in a substantial proportion of myeloid and erythroid colony-forming cells and sorted T- and B lymphocytes. The blood counts were stable for about 20 years despite an 11q23 deletion in the residual non-revertant cells which led to MDS subsequently developing. In a second report in monozygotic twins (patients 2A and 2B), Mankad A et al. [78] demonstrated increased sensitivity to DNA cross-linking agents in skin fibroblasts and not the lymphocytes or committed hematopoietic progenitors. Expectedly, molecular analysis of *FANCA* revealed two mutations in the skin [a frameshift causing deletion in exon 27 (c.2555delT) and an exon 28 missense mutation (c.2670G>A/p.R880Q)]. Surprisingly, an acquired exon 30 missense change (c.2927G>A/p.E966K) was detected only in the hematopoietic cells and in neither parent. This compensatory mutation existed in cis with the maternal exon 28 mutation, restoring function. Both sisters were free of hematologic symptoms for more than 20 years. Gross et al. [79] described the types of reversions in five mosaic FA patients who were compound heterozygotes for single base mutations in *FANCA* or *FANCC*. Intragenic crossover could be shown as the mechanism of self-correction in a *FANCC* patient. Restoration to wildtype via back mutation or gene conversion of either the paternal or maternal allele was observed in the *FANCA* patients. The environments of these reversions were indicative of high mutability. As in two patients, Gross also demonstrated in vitro phenotypic reversion as a result of the emergence of a compensating missense mutation 15 amino acids downstream of the constitutional mutation. In this series, four of five patients showed improvement of their hematologic status during a limited follow-up period.

Regardless of the mechanism for the genetic reversion, the event is relatively common in T cells of FA patients and very rare in the HSC. As genetic reversion should be a rare event, hematopoiesis should be clonal. X-inactivation studies in the monozygotic twins confirmed clonality. Notably, this has also been observed in an unreported case with clonal hematopoiesis confirmed by X-inactivation studies (JE Wagner & AD Auerbach, unpublished data). Like the prior cases, hematopoietic progenitors were insensitive to low doses of MMC, paralleling the dose–response curve of progenitors from an unaffected donor (Figure 76.8).

While it is clear that many FA patients may have mosaicism in the T-cell compartment [12], this observation does not predict

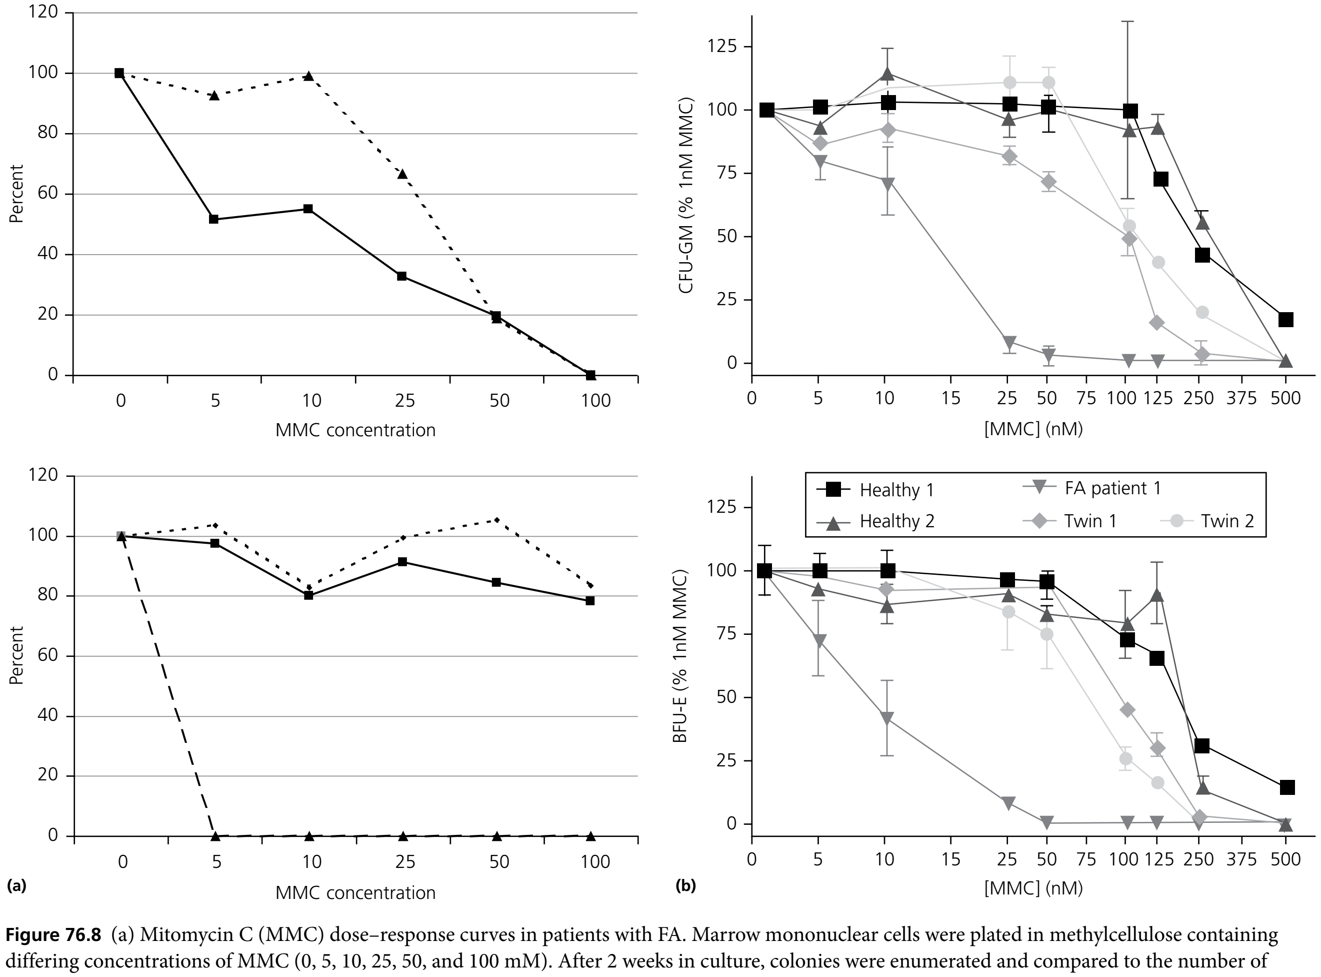

Figure 76.8 (a) Mitomycin C (MMC) dose–response curves in patients with FA. Marrow mononuclear cells were plated in methylcellulose containing differing concentrations of MMC (0, 5, 10, 25, 50, and 100 mM). After 2 weeks in culture, colonies were enumerated and compared to the number of colonies in the untreated control. Results demonstrate the colony-forming cell (CFC) MMC resistance in Patients 1 and 2. The upper panel (patient 1) demonstrates partial resistance; the lower panel (patient 2) demonstrates complete MMC resistance comparable to marrow CFCs from a normal healthy volunteer. The dashed line in the lower panel reveals marked MMC sensitivity of marrow progenitors obtained from the patient's affected sibling. (b) MMC dose–response curves of bone marrow derived clonal progenitors from one Fanconi anemia patient (FA Patient 1), two healthy volunteers (Healthy 1 and 2), and twins (Twin 1 and 2) are shown with CFU-GM in (A) and BFU-E in (B). (b) Source: Mankad et al. 2006 [78]. Reproduced with permission of the American Society of Hematology.

mosaicism in hematopoietic progenitors. Certainly, HSC mosaicism may be associated with normal blood counts at least for decades. The clinical significance of T-cell mosaicism is unclear. Some reports suggest a higher risk of graft rejection in patients with DEB resistant T cells [80]. Perhaps revertant host T cells survive the FA dose-adjusted chemoradiotherapy and are capable of rejecting the transplanted HSC. More recent reports, however, do not demonstrate such an association perhaps due to the increased use of fludarabine, a potent immunosuppressant.

Why this is significant to the transplant team? In addition to genotype, the presence of somatic mosaicism may be of important predictive value regarding the clinical course of the patient with FA. While marrow failure may be less likely in those few patients with genetic reversion in the HSC, perhaps the more important impact of somatic mosaicism is the diagnostic challenge it might impose. As outlined in Figure 76.5, if there is a high clinical suspicion of FA based on morphologic parameters or genetic history (all the cases above had affected siblings), a skin biopsy should be considered. In addition, somatic mosaicism originating in a pluripotent HSC can be viewed as "spontaneous" or "natural" gene therapy. The clinical course of the patients described earlier may be instructive with regard to the future potential of autologous HSC gene therapy for this disease. The main premise of gene therapy in FA patients is that corrected FA cells will have a proliferative advantage over non-corrected cells. In the cases described earlier, hematopoietic function was distinctly better than that in affected siblings. However, the first case raised the possibility that HSC gene correction alone may not be sufficient. This case illustrates the potential risk of myelodysplasia in residual FA HSCs with eventual suppression of normal hematopoiesis. Therefore, the risk of malignant transformation of residual FA HSCs remains a risk and suggests the need to eradicate residual non-reverted stem cells in those with somatic mosaicism (and uncorrected stem cells after gene therapy).

Genotype–phenotype correlations

As molecular data have become increasingly available, we can now explore the possibility of genotype–phenotype correlations. While it would be helpful to know which patients are at higher or lower risk of early marrow failure, leukemia, or solid tumors, this has turned out to be the exception rather than the rule. Today, there are only a few subgroups of patients for whom we can reliably predict a higher risk of cancer and early marrow failure.

In a retrospective analysis, the IFAR data [18] confirmed that specific complementation groups play a significant role in both the timing of bone marrow failure and survival (Figure 76.6). FA-C patients, for example, have a significantly earlier onset of bone marrow failure (Figure 76.6) and poorer survival compared to FA-A and FA-G patients As reported by Gillio et al. [81], patients with *FANCC* genotypes can be divided into three clinical groups: (i) patients with the c.456+4A>T (IVS4) mutation; (ii) patients with at least one exon 14 mutation (p.R548X or p.L554P); and (iii) patients with at least one exon 1 mutation (c.322delG or p.Q13X) and no known exon 14 mutation. IVS4 and exon 14 subgroups are associated with a severe phenotype manifested by multiple major congenital malformations, early onset of hematologic disease and poorer survival compared to exon 1 patients and to the non-FA-C IFAR population (Figure 76.9) [18].

However, it is the group of patients with mutations in FANCD1/BRCA2 that have the most conspicuous genotype–phenotype correlations. While there are similarities in the response to clastogenic agents, abnormal skin pigmentation, intrauterine growth retardation and short stature, biallelic mutations in *FANCD1/BRCA2* are associated with an extremely high predilection to leukemia and cancer at a very early age [82]. For all patients with biallelic mutations in *FANCD1/BRCA2*, the incidence of leukemia is 41% at age 5 years in contrast to FA in general where incidence is 1% during the first 5 years of life (Figure 76.10). In addition, biallelic *FANCD1/BRCA2* mutations are also associated with development of solid tumors, most often of the brain and kidney [83]. Of interest, medulloblastoma is particularly common in children of Ashkenazi Jewish descent who carry the BRCA2 founder mutation c.6174delT. The only other FA patients with a similar phenotype have mutations in another downstream factor, FANCN. Biallelic mutations in the BRCA2-interacting protein PALB2 (*FANCN*) is associated with embryonal cancers and early death [84]. As expected, the family history is particularly important in BRCA2 families, as many (but not all) of these kindreds have significant histories of breast and other cancers.

Neveling et al. [85] has also reported that some phenotypes are more likely found in specific complementation groups. For example, patients with the most mild phenotype are absent in complementation groups B, E, and F. Similarly, patients with the few congenital anomalies but high risk of cancer more commonly fall within the FANCA and FANCD2 groups.

Why this is significant to the transplant team? The ability to correlate genotype with outcome has considerable clinical significance. While the exception, some genotypes are associated with the pace of hematologic abnormalities, cancer risk, and survival. This knowledge aids the family and clinician in timing the various treatment options as well as prescribing a tailored surveillance plan. For example, patients with *FANCC* IVS4 or exon 14 mutations or biallelic mutations in BRCA2 should be followed more closely for early marrow failure and development of clonal cytogenetic abnormalities and, in the case of BRCA2, prophylactic allogeneic HCT might be considered.

Non-transplant treatment strategies

Androgens

Primary treatment for bone marrow failure in patients with FA has historically been androgens with or without prednisone. Androgen therapy (most commonly oxymetholone initiated at 2 mg/kg/day) was first evaluated in patients with FA by Shahidi and Diamond [86]. Hematologic improvement occurs in 50% [87]. Patients responding to androgens typically do so within several months of drug initiation [88]. In addition, prednisone (5–10 mg every other day) was frequently added in an attempt to promote vascular stability and decrease bleeding tendency in those with severe thrombocytopenia [88]. For those that respond, Alter and Young [88] observed a 3-year survival advantage in those treated with androgens versus other non-HCT treatments.

Very recently, some hematologists have argued for androgens for all newly diagnosed FA patients based on the fact that some patients may avoid transplant altogether and a recent unpublished observation that a switch in androgen formulation may further prolong the response to androgen and thus delay HCT. Certainly, the use of androgens should be considered for any patient who is considered a poor risk candidate for HCT. However, for the good HCT candidate, androgens are generally not considered because of the high survival rates expected after

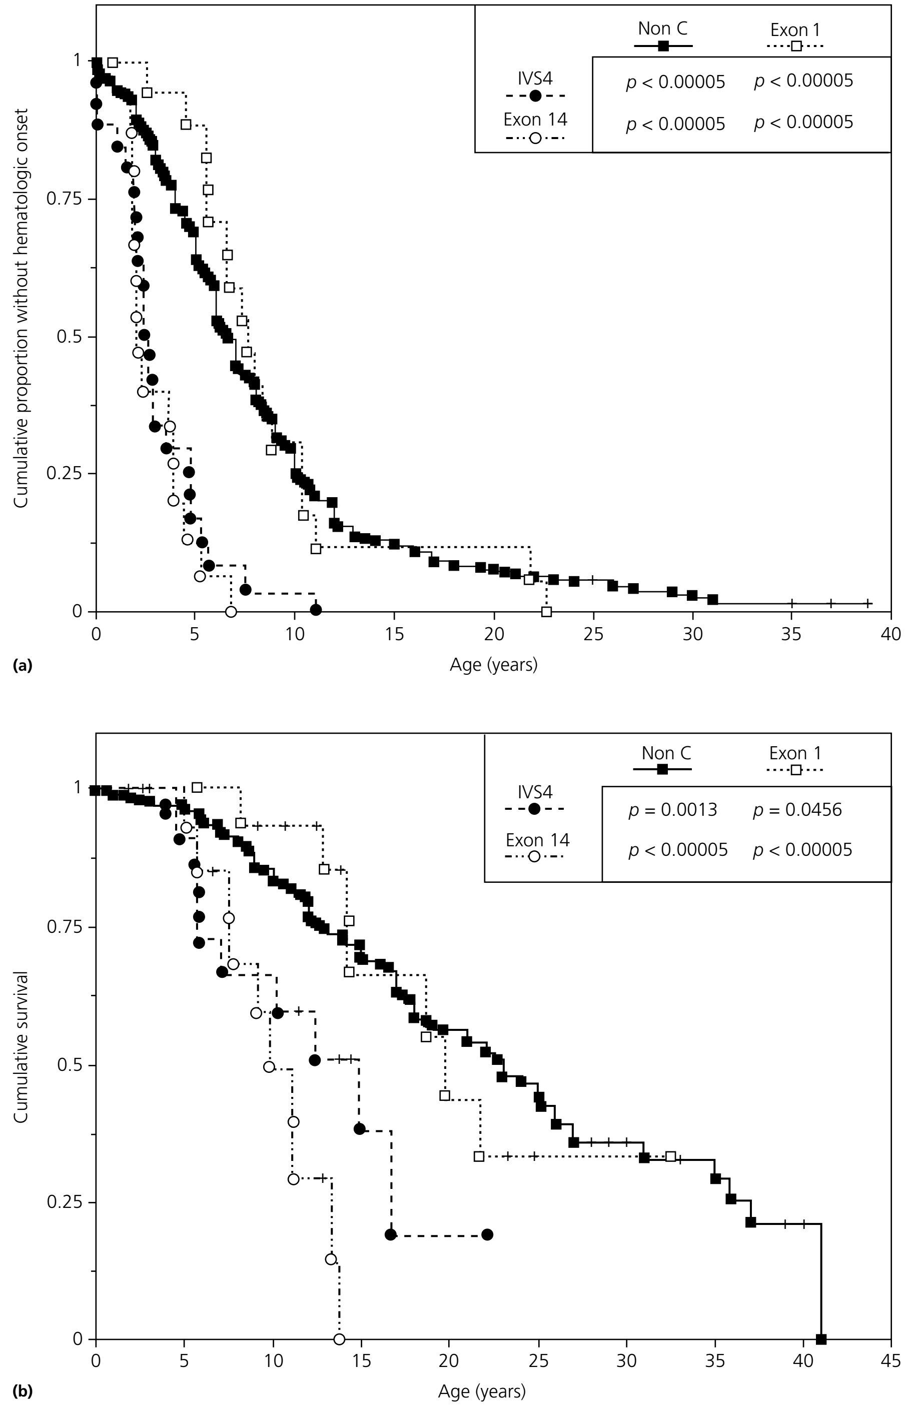

Figure 76.9 Within complementation group C patients ($n = 78$ in the IFAR database) marrow failure occurs at an earlier time point in patients with at least one intron 4 (IVS4+4A>T) or at least one exon 14 (*R548X* or *L554P*) mutation ($n = 50$) compared to patients with at least one exon 1 mutation (*322delG* and *QX13*) and no mutations in exon 14 or intron 4 ($n = 27$). (a) The median age of hematologic disease onset is a 2.7 years (range 0 to 11 years) in the IVS4 group and 2.1 years (range 0.8 to 5.2 years) in the exon 14 group. In comparison, the exon 1 subgroup displays a mild phenotype with few major congenital malformations and a median age of onset of hematologic disease is 7.6 years (range 2.6 to 21.8 years). (b) Earlier hematologic disease onset and a greater number of congenital malformations are associated with poorer survival. IVS4 and exon 14 subgroups experienced median survivals of 14.9 and 9.7 years, respectively. In contrast, exon 1 patients had a median survival of 19.7 years ($p < 0.00005$). transplant and potential deleterious effect of androgens on transplant outcome. The physical, mental and psychologic effects, including increased acne and body hair, voice change, testicular shrinkage, acne, mood swings, aggressiveness, mania and depression, cannot be underemphasized. In addition, patients on androgens must be monitored for peliosis hepatis, hepatic adenomata and hepatocellular carcinoma (Figure 76.11) by ultrasound, computerized tomography and/or magnetic resonance imaging

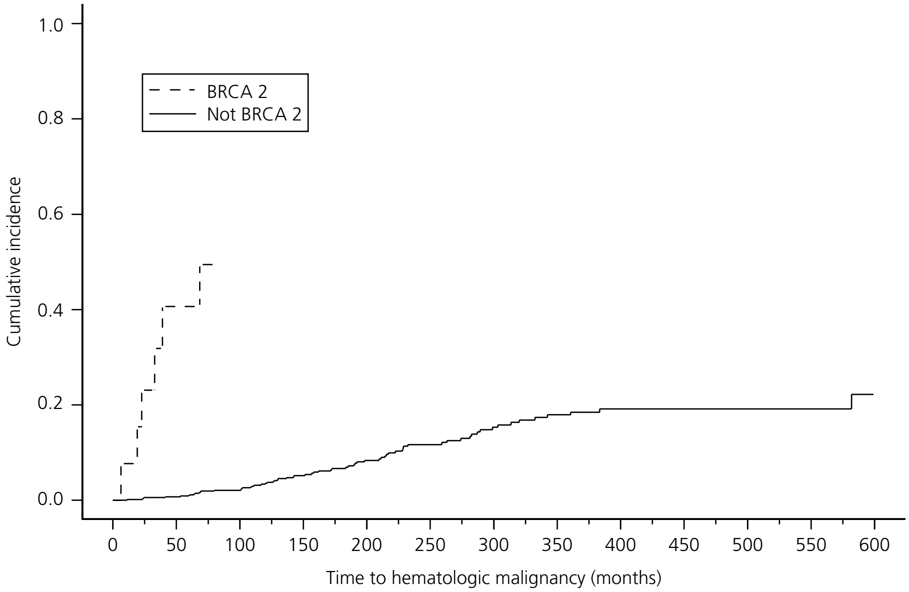

Figure 76.10 Cumulative incidence of hematologic malignancy among *BRCA2* mutation carriers (14 patients) versus all other complementation groups in the IFAR (746 patients). Among FA patients with biallelic mutations in BRCA2, the cumulative incidence of hematologic malignancy is 41% (95% CI, 20–85%) at 5 years of age. In contrast, the incidence of hematologic malignancy in non-*BRCA2* FA patients in the IFAR registry at 5 years is 1% (95% CI, 0.5–2.1%). Source: Wagner et al. 2004 [82]. (For a color version of this figure, please see the color plate section.)

and alpha fetoprotein levels. Multiple reports in the transplant literature suggest that prior exposure to androgens is an adverse risk factor, limiting the successful use of transplant. As detailed later in "Hematopoietic cell transplantation," outcomes with HCT are no longer poor, making such a recommendation for use of androgens more challenging.

In contrast to idiopathic aplastic anemia, use of antithymocyte globulin (ATG), cyclosporine, high-dose methylprednisolone and other immunosuppressants should have little impact if the mechanism of FA aplasia is loss of the HSC due to constitutive hypersensitivity to TNF-α and IFN-γ or aldehyde toxicity rather than immune attack [73–76]. While there have been some anecdotal reports of benefit after immunosuppression [88], immunosuppressive therapy is generally not expected to be an effective strategy for patients with FA, although this has never been formally evaluated.

Vitamins and antioxidants

Shahidi and others have recommended the use of antioxidants to potentially reduce free radical oxygen toxicity that may play a role in the pathogenesis of the progressive marrow failure and epitheliod malignancy observed in patients with FA [90]. Daily intake of beta-carotene, vitamin C, vitamin E, and selenium has been suggested. A clinical trial with quercetin, a plant flavonoid, has recently been opened to evaluate the safety and optimize the dose. Whether such therapies alter the natural history of marrow failure or risk of hematologic or non-hematologic malignancies (i.e., cervical carcinoma or head and neck cancers) in FA patients is unknown. In contrast, there is probably a role for folic acid and iron supplementation in those receiving therapy to increase the red cell mass. Iron levels, however, should be evaluated prior to the initiation of iron supplementation as some patients will already have excess iron stores for unclear reasons.

Hematopoietic growth factor therapy

Only two pilot studies [91,92] have been reported on the safety and efficacy of hematopoietic growth factor therapy in the treatment of neutropenia in patients with FA nearly a decade ago. While GM-CSF and G-CSF have both been used successfully to increase the neutrophil counts with little systemic toxicity, it is unknown whether such therapy will alter the risk of MDS, development of clonal cytogenetic abnormalities or risk of leukemia, if used long term. Erythropoietin has also been used to increase red cell counts and decrease the need for red cell transfusions but no formal study has been published. However, the fact that many FA patients have highly elevated endogenous erythropoietin levels may limit the usefulness of this treatment in the majority. While long-term use of hematopoietic growth factor therapy has not been studied, the most common use in FA patients is as a bridge to transplant or immediately after transplant to speed neutrophil recovery from the donor graft.

Supportive care

Eventually, FA will result in marrow failure, necessitating blood product support for treatment of thrombocytopenia and anemia. Epsilon-aminocaproic acid and hematopoietic growth factor therapy with antibiotics are short-term remedies for FA patients with thrombocytopenia and bleeding or neutropenia and fever, respectively. For the patient not pursuing allogeneic HCT as a treatment option whether because of severe comorbidities, age, or lack of a suitable donor, such combination therapy can aid in sustaining life for years. Risk of iron overload, however, should be minimized by early chelation therapy. For the patient considering allogeneic HCT, use of red cell and platelet transfusions should be avoided if possible to reduce the risk of alloimmunization. If transfusions are required, an effort should be made to transfuse only irradiated, cytomegalovirus-negative (or filtered) red cell or single donor platelet products. Whether specific, selected volunteer donors should be identified to limit exposure to human leukocyte antigens (HLAs) has not been proven. As detailed in the next section, history of transfusions and prior opportunistic infections are adverse risk factors after transplant. Therefore, moving to transplant prior to severe cytopenia would be advantageous if it is possible.

It is important that the clinician consider strategies for reduced exposure to agents potentially affecting hematopoiesis even though a decline is ultimately unavoidable in most FA patients. For example, every effort should be made to avoid marrow suppressive drugs, such as antibiotics, like Bactrim®, often used in the treatment of chronic otitis media or urinary tract infections. As summarized earlier in "Mechanisms of marrow failure," FA HSC hypersensitivity to TNF-α argues for examining ways for reducing exposure to viruses generally and TNF-α specifically. While it is not possible to eliminate all exposures, young children with FA should be immunized against Varicella-Zoster virus and influenza which has been associated with severe marrow suppression after such viral infections. Alternatively, treatment with anti-TNF-α receptor Fc fusion protein (Etanercept; Enbrel) may prevent or reduce the rate of progression of marrow failure in children and adults with FA. This study was recently completed and results are pending.

Hematopoietic cell transplantation

As of 2015, allogeneic HCT remains the only treatment with the potential of correcting the hematologic manifestations of FA. Although allogeneic HCT for FA is still associated with risk, the risk profile has substantially diminished over time. Poor outcomes in the 1980s and 1990s were primarily the result of excessive regimen-related toxicity (RRT), graft failure and severe acute graft-versus-host disease (GVHD) [93–96]. The earliest conditioning regimens were based upon those designed for patients with acquired AA and acute leukemia, administering cyclophosphamide (CY) at doses of 200 mg/kg with or without irradiation and cytotoxic agents. This dismal early clinical experience prompted in vitro laboratory studies that confirmed the hypersensitivity of FA cells to alkylating agents [97,98] and irradiation [99]. As a result, Gluckman et al. proposed the use of low-dose CY (20 mg/kg) and single fraction of thoraco-abdominal irradiation (TAI, 500 cGy) in the early 1980s, resulting in markedly reduced RRT and enhanced survival after HLA-matched sibling donor HCT [100]. Besides better donor-recipient HLA matching and supportive care applied to all patients, the specific addition of fludarabine (FLU) and incorporation of marrow T-cell depletion reduced the risks of graft rejection and severe GVHD, leading to improved survival. Current efforts are now aimed at reducing the risks of opportunistic infections and late effects, especially endocrinopathies, infertility, and malignancy [101].

HLA-identical sibling donor HCT

Historical perspective

For FA patients with HLA-identical sibling donors, HCT using the Gluckman strategy of reduced-intensity radiation was generally associated with excellent outcome if performed prior to the development of MDS or leukemia, and within the first two decades of life. Factors associated with higher survival included younger age at transplant, higher pre-transplant platelet count, lower dose conditioning regimen, and improvements in GVHD prophylaxis [94]. In an analysis of 209 FA patients with an HLA-identical sibling donor transplanted between 1994 and 1999, the 3-year survival was 81% in patients aged <10 years of age ($n = 109$) and 69 ± 10% in older patients ($n = 100$) (Figure 76.12) [102]. Since that time, survival has only continued to improve in most series.

Current results

Today fewer patients with an HLA-identical sibling donor receive radiation in an attempt to reduce the late effects commonly associated with radiation. Outcomes with and without irradiation are summarized in Tables 76.3 and 76.4 [103–110]. Bonfirm et al. [110] reported results in 85 FA patients (median age 9 years, range 3–34) treated in Brazil between 1999 and 2011. Patients either had aplastic anemia ($n = 82$) or MDS ($n = 3$), were conditioned with CY 15 mg/kg × 4 days (60 mg/kg total dose) and received methotrexate (MTX) and cyclosporine (CSA) as GVHD immunoprophylaxis. All patients received bone marrow from HLA-identical siblings ($n = 74$) or other relatives ($n = 11$). Neutrophil recovery occurred in 77/83 (93%) with primary graft failure in two and secondary graft failure in four, occurring at a median of 244 (range, 152–365) days after HCT. Of the six patients with graft failure, four are alive after second transplant using the same donor. Notably, all three patients with MDS relapsed after HCT and died from progressive disease despite second transplant. Overall, the survival is 85% at 5 years with 96% survival in those aged <10 years ($n = 48$) at the time of transplant. Of the 81 evaluable patients, 17 developed grade II–IV and 7 grade III–IV acute GVHD. Of 78 evaluable for chronic GVHD, 23 had chronic GVHD (extensive in 12). In multivariate analysis, only acute and chronic GVHD were factors associated with lower overall survival. Transplant-related mortality at day 100 and 1 year were 6% and 10%, respectively, with the major causes of death being graft failure and GVHD. To date, four patients have developed squamous cell carcinoma (SCC) of the oral cavity between 2 and 5 years after HCT with all SCC patients having had a history of extensive chronic GVHD with oral mucosa involvement with only one alive and free of disease.

In an attempt to reduce the risk of acute and chronic GVHD, Tan and MacMillan et al. ([105], updated by M MacMillan, personal communication) incorporated ex vivo and in vivo marrow T-cell depletion. Based on promising results by Aker et al. [111], patients were conditioned with CY 5 mg/kg × 4 days (20 mg/kg total dose), FLU 35 mg/m^2 × 5 days (175 mg/m^2 total dose), and antithymocyte globulin 30 mg/mg × 5 days (ATG; 150 mg/kg total dose) followed by the infusion of T-cell-depleted marrow by CD34 selection with CsA and methylprednisolone [and later mycophenolate mofetil (MMF)] immunoprophylaxis. Thus far, 23 patients (median age 8.5 years; range: 3.2–43.3) have been treated [bone marrow in 15 and umbilical cord blood (UCB) in 8] [105]. Primary neutrophil recovery occurred in 100% and no patient had grade III–V regimen-related toxicity with only one patient having grade II–IV acute GVHD and one chronic GVHD. The overall survival is 82% at 5 years with a median follow-up of 5.4 years (range 2.1–11.2 years). Transplant mortality at day 100 and 1 year was 4% and 13%, respectively. To date, no patient has developed SCC. Of the three deaths, one each died of chronic GVHD, recurrent MDS, and donor-derived AML. This regimen was also used in one other patient with an HLA-matched maternal donor who died from chronic GVHD after a second HCT for the treatment of secondary graft failure.

In 2008, on behalf of the CIBMTR, Pasquini et al. [112] compared transplant outcomes in recipients conditioned with (n = 77) and without (n = 71) irradiation-containing regimens prior to HCT with HLA-identical sibling donors. Hematopoietic recovery, acute and chronic GVHD, and mortality were similar between the two groups. In multivariate analysis, higher mortality was associated with age >10 years, prior use of androgens, and cytomegalovirus (CMV) seropositivity in either the donor or recipient. With a

median follow-up of more than 5 years for both groups, the overall survival was 78% and 81% at 5 years ($p = 0.61$), respectively. Whether a difference in late effects, for example infertility/sterility, cataracts, endocrinopathies or risk of SCC, remains to be determined. While not yet proven, use of radiation may be important in those with MDS or more advanced disease.

Alternative donor HCT

Unfortunately, the majority of FA patients do not have an HLA-identical unaffected sibling donor. Although deliberate conception and in vitro fertilization (IVF) with preimplantation genetic diagnosis (PGD) have been considered as a means to have a healthy sibling that is also HLA identical with the existing child with FA ([113,114], see "Genetic counseling"), time, maternal age, cost and personal beliefs limit its wider use. However, the need for such an option has decreased as the results with alternative (i.e., an HLA-mismatched related or HLA-matched or -mismatched unrelated) donor HCT are increasingly comparable to that observed after HCT with an HLA identical sibling donor.

Historical perspective

Before 2000, the principal obstacle to the successful use of alternative donor HCT was graft failure. Excessive conditioning led to unacceptable rates of regimen-related toxicity. Insufficient conditioning led to unacceptable rates of graft failure. Overall, approximately 25–35% of FA patients failed to engraft after alternative donor HCT [94–96]. Conditioning regimens most often consisted of CY (15–25 mg/kg), TBI (300–800 cGy) with or without ATG. In some cases, the presence of DEB-resistant T cells may have increased the risk of graft rejection; however, in others it was likely multifactorial potentially due to HLA mismatch, early infections and/or the presence of anti-HLA antibodies in those heavily transfused. After 2000, with the addition of FLU to the conditioning regimen, the risk of graft failure dramatically decreased. Based on early observations, many centers incorporated FLU into the conditioning regimen with markedly improved results [115–119]. In 2007, Wagner et al. [80] reported the outcomes of unrelated donor HCT in patients with FA ($n = 98$) on behalf of the CIBMTR. This was the first multi-institutional analysis documenting improved engraftment in recipients of FLU-containing regimen compared to those without FLU (Figure 76.13). MacMillan et al. [119] more recently reviewed the outcomes of FA patients who underwent alternative donor HCT at the University of Minnesota since 1990. While higher dose TBI (600 cGy) failed to reduce the risk of graft failure, addition of FLU significantly enhanced the probability of neutrophil recovery ($p < 0.01$). Recipients of a FLU-based regimen were nearly three times more likely to achieve neutrophil engraftment (RR 2.9; 95% CI, 1.6–5.1; $p < 0.01$). Use of androgens prior to HCT (RR 0.6; $p = 0.04$) and UCB (RR 0.2; $p < 0.01$) as a stem cell source were two factors adversely affecting engraftment.

The second major hurdle to successful alternative donor HCT was GVHD. In 2000, Guardiola et al. [95] on behalf of the European Group for Blood and Marrow Transplantation (EMBT) and the European Fanconi Anemia Registry reported the outcomes of unrelated donor HCT in 69 patients with FA and found that GVHD was the primary cause of death ($n = 22$). The incidence of grade II–IV and grade III–IV acute GVHD was 43% and 34%, respectively. In multivariate analysis, factors associated with GVHD were absence of T-cell depletion (RR, 20.0; $p = 0.004$), malformations of the urogenital tract and/or the kidneys (RR, 6.60; $p < 0.02$), elevated serum alanine/aspartate transaminases prior to conditioning (RR, 2.52; $p < 0.04$), and limb malformations (RR, 2.55; $p < 0.04$). In a more recent CIMBTR analysis, Wagner et al. [80] reported a high risk of grade II–IV acute GVHD in recipients of a non T-cell-depleted graft (RR, 4.29; 95% CI, 1.82–10.10; $p < 0.001$). In the cohort conditioned with FLU, the incidence of grade II–IV acute GVHD at day 100 was 70% and 21%, respectively in FA recipients of non T-cell-depleted and T-cell-depleted bone marrow. At the University of Minnesota, T-cell depletion (first with counterflow elutriation and subsequently with CD34 selection) was incorporated into the treatment protocol in 1994. Comparing T-cell-depleted marrow to T-replete marrow and UCB, the incidence of grade II–IV acute GVHD was significantly lower in recipients of T-cell-depleted marrow (18%) as compared to 50% and 38% in recipients of T-replete marrow and UCB, respectively ($p < 0.01$). Similarly, grade III–IV acute GVHD was also significantly lower in T-cell-depleted marrow recipients (6% vs. 38% vs. 21%, respectively; $p < 0.01$). T-cell depletion also reduced the incidence of chronic GVHD (9% vs. 25% vs. 17%; $p < 0.04$). In a report by Eurocord–Netcord and the EBMT, similar rates of acute GVHD (32%) and chronic GVHD (16%) were observed in UCB recipients [120]. Importantly, in a retrospective analysis of 37 FA patients who underwent HLA-identical bone marrow transplantation at the Hôpital Saint Louis, grades II–IV acute GVHD was a significant predictor of head and neck SCC, which was only observed in FA patients experiencing one of these two complications. The 10-year cumulative incidence of head and neck SCC in FA patients experiencing grades II–IV acute GVHD was 28% versus 0% for patients without GVHD [121].

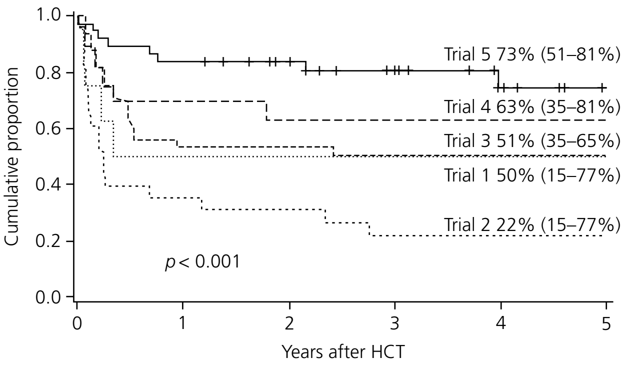

Figure 76.13 Probability of survival after alternative donor HCT for the treatment of patients with standard risk FA at the University of Minnesota between 1990 and 2012. One hundred and twenty-seven FA patients underwent AD-HCT at the University of Minnesota using one of five consecutive, prospective phase I–II total clinical trials. Trial 1: CY40 mg/kg + TBI 450 cGy + T-replete marrow; Trial 2: CY40 mg/kg + TBI 450 cGy + ATG + T-depleted marrow or UCB; Trial 3: CY40 mg/kg + FLU 140 mg/m^2 + TBI 450 cGy + ATG + T-depleted marrow or UCB; Trial 4: CY40 mg/kg + FLU 140 mg/m^2 + TBI 450 cGy (with thymic shielding) + ATG + T-depleted marrow or UCB; and Trial 5: CY40 mg/kg + FLU 140 mg/m^2 + TBI 300 cGy (with thymic shielding) + ATG + T-depleted marrow or UCB.

As shown in Figure 76.12, FA patients transplanted with marrow from alternative donors 15–20 years ago had survival rates <30% with excessive rates of regimen-related toxicity, graft rejection, GVHD, and opportunistic infections being major obstacles [94]. However, improvements in HLA typing and supportive care as well as changes in the treatment protocol led to series of incremental improvements that together completely alter the expected outcome for FA patients transplanted with marrow or UCB from an alternative donor today (Table 76.5).

Regardless of donor type, transplant outcome is markedly influenced by the disease status at the time of HCT. As expected, FA patients with either advanced MDS (≥5% blasts) or leukemia have a significantly lower probability of survival. The apparent successful eradication of the malignant clone in some patients with generally reduced doses of chemotherapy with or without transplant suggests that the malignant cells carry a similar hypersensitivity to alkylating agents and irradiation, characteristic of FA non-malignant hematopoiesis [122–124].

Current expectations

Today, it is expected that donors can be found for most everyone with a high likelihood of survival after HCT performed at centers experienced in FA. At the University of Minnesota, 48 patients with FA (age range 1.7 to 34.3) with lineage cytopenia and aplastic anemia in most, received FLU, CY, ATG, and low dose TBI (300 cGy) followed by T-cell-depleted 7–8/8 HLA-matched bone marrow ($n = 32$) or HLA-mismatched umbilical cord blood ($n = 16$) if an unrelated donor was unavailable. All recipients of marrow engrafted at a median of 11 days (range, 9–23). In contrast, the incidence of engraftment was 88% at a median of 19 days (range, 10–40) in recipients of UCB. The incidence of acute and chronic GVHD was low at 12% and 6%, respectively, with similar outcomes in patients transplanted with marrow and UCB. The overall survival for the entire cohort was 78% at a median of 2.9 years (range 0.6–6.3). Survival appears superior in recipients of marrow relative to those transplanted with UCB. In 2014, MacMillan et al. [123] also reported on 21 FA patients with AML ($n = 16$), acute lymphocytic leukemia (ALL; $n = 2$), or advanced MDS with >5% blasts ($n = 3$) treated with alternative donor HCT between 1988 and 2009 [123]. Five patients had biallelic FANCD1/BRCA2 mutations. Only two of seven patients who received chemotherapy before HCT achieved remission both of whom had FANCD1/BRCA-2 mutations and T-cell ALL. For the entire cohort, the median age was 15.5 (range 1.1–48.5) years. Median age for FANCD1/BRCA2 patients was substantially lower at 1.9 (range 1.4–6.6) years. Patients received CY, ATG, and either single fraction TBI ($n = 15$) or busulfan (BU) ($n = 6$), with FLU in 11, followed by alternative HCT in 18. GVHD prophylaxis consisted of CSA and MP. Probability of neutrophil engraftment was 75% without FLU and 100% with FLU-based regimens. Probability of acute GVHD was 19%. For the entire cohort, probability of survival at 1 year was 43% with a higher survival (60%) in the 11 patients who received a FLU-based regimen. In these 11 patients, the incidence of relapse was 21%. These data suggest that HCT with a FLU-based preparative regimen offers potential curative therapy for FA patients with acute leukemia or advanced MDS. Except perhaps for FANCD1/BRCA2 patients with T-cell ALL, there was no clear role for chemotherapy prior to HCT in FA patients with AML or MDS.

Recently, the results of a multi-institutional study were reported [125] exploring a non TBI-containing regimen in patients undergoing unrelated donor HCT. Between 2009 and 2012, 27 patients (median age 8.1 years) most often with lineage cytopenia or aplastic anemia (78%) received FLU, CY and ATG in combination with BU followed by transplantation of T-cell-depleted peripheral blood stem cells. All patients engrafted with one having secondary graft failure. Grade II–IV GVHD occurred in only one patient. Grade II–IV toxicities included pulmonary and hepatotoxicity ($n = 6$ for each) with one patient developing hepatic veno-occlusive disease. Although the median follow-up was short (<8 months, range 0.5–37.8 months), 19 of 23 with sufficient follow-up were alive at the time of the report. Deaths were due to acute respiratory failure, multiorgan failure, severe pulmonary hypertension, and infection.

Summary

Together, the clinical data suggest:

1. A good survival outcome can be expected for FA patients transplanted with either an HLA-identical sibling or unrelated donor HSC especially when the patient is young, has had few red cell and/or platelet transfusions, and prior to the development of MDS or leukemia.
2. HCT without radiation is increasingly the norm in FA patients with an HLA-identical sibling donor. Reduced exposure to DNA cross-linking agents, such as high-dose CY or irradiation, minimizes the risk of early and late toxicities, including ovarian failure and endocrinopathies beyond that inherent in the disease. In contrast higher dose therapy is generally required for HCT using alternative donors. While the largest experience is with low-dose CY in combination with FLU and lower dose TBI prior to the infusion of T-cell-depleted marrow or UCB,

higher dose CY alone prior to T-replete HSC has met with similar early survival outcomes. Encouraging early results have also been reported (but not yet published) with BU, CY and FLU prior to T-cell-depleted marrow or UCB. In contrast to some non-US centers, T-cell depletion has been favored in the USA in an attempt to reduce the risks of acute and chronic GVHD, the only known risk factors for SCC in FA patients treated by HCT. As early survival has markedly improved, it should be clear in the near future what the impact of T-cell depletion is on SCC risk.

3 HCT without prior chemotherapy has curative potential in some FA patients with advanced MDS and acute leukemia. It is unclear whether pre-transplant chemotherapy to reduce the leukemia burden has any impact on long-term survival. For patients with preexisting severe comorbidities or older age (for example, age >35 years), alternate therapies, such as with androgens, transfusions with chelation, and/or hematopoietic growth factors, should be considered rather than HCT.

Over the last two decades sequential changes to the approach to alternative donor HCT has resulted in significant improvements. The two pivotal changes have been the addition of FLU to improve engraftment rates and the use of T-cell depletion to reduce GVHD. Improved outcomes are also due in part to the fact that FA patients are referred prior to the development of advanced MDS, leukemia, and opportunistic infections. Despite substantial improvement in survival, the greatest effort needs to be focused on reducing the morbidities associated with transplant, especially caused by toxicity and opportunistic infections. Additionally, emphasis is now being placed on developing approaches to HCT, which will improve quality of life by reducing late effects, particularly the risk of malignancy, sterility, and endocrinopathies. In light of the complexity of FA, it is recommended that HCT for FA be performed at select centers experienced in the care of FA patients with and without transplant, which will also provide long-term care monitoring for late effects of the disease and therapeutic interventions employed. A treatment algorithm for FA patients with bone marrow failure, MDS, or leukemia is proposed (Figure 76.14).

Cancer risk after HCT

As previously stated, FA is characterized by a marked predisposition to leukemia and solid tumors. In contrast to the general population, these cancers occur at remarkably young ages likely secondary to the underlying DNA repair defect and genomic instability. In order to better understand the relative risk of cancer after transplant, Rosenberg et al. [126] surveyed FA patients with and without transplant in the USA and in Canada. In this study 27 cancers were observed in 23 individuals of 145 respondents. Of the 27 cases, 18 had solid tumors. In contrast to the median age of leukemia diagnosis (11.3 years, range: 3–24 years), FA patients with solid tumors were older (28.9 years, range: 7–45 years). Remarkably, the observed-to-expected ratio of solid tumors of the head and neck, esophagus and vulva was 706, 2362, and 4317, respectively, relative to age-matched controls. For FA patients, the relative risk of cancer remained low (9%) until age 28 years. By ages 34 and 48 years, the relative risk was 22% and 29%, respectively. As shown in Figure 76.2, the rise in relative risk of solid tumors is non-linear and without a plateau. Reports from the IFAR are similar with a 28% incidence of solid tumors by age 40 [11]. While numerous types of solid tumors have been observed (Table 76.6), there is a marked predisposition toward SCC, especially of the upper aerodigestive and anogenital regions. Compared to the Surveillance, Epidemiology and End Results (SEER) of the general population, FA patients have a 500-fold higher risk of solid tumors [18].

In 1996, Deeg et al. [127] published the seminal paper on the risk of cancer after HCT for FA or severe aplastic anemia. In an analysis of 700 patients (79 with FA and 621with non-FA aplastic anemia) treated with allogeneic HCT in Seattle or Paris, the Kaplan–Meier estimate for developing any malignancy by 20 years after HCT was 14%. Among patients with FA, a single hazard peak for solid tumors occurred between 8 and 9 years after HCT with a probability of developing any malignancy of 42% (95% CI,

AML, acute myeloid leukemia.

10–74%) by 20 years after HCT with all being solid tumors. In multivariate analysis, two factors were found to be associated with risk of cancer, a diagnosis of FA (RR, 11.2; $p = 0.0001$) and treatment with azathioprine (RR, 11.7; $p = 0.0001$) used for the treatment of chronic GVHD. Within the group of patients with aplastic anemia, use of radiation was another factor associated with cancer risk. Importantly, the effect of radiation on cancer risk could not be independently evaluated in the FA cohort because use of radiation was the standard practice. Still, this study had a profound impact on the FA community.

In 2005, Rosenberg et al. [128] evaluated the risk of SCC and death in patients with FA who did and did not receive HCT. The transplant cohort ($n = 117$) underwent transplant at the Hôpital St. Louis; non-transplanted patients ($n = 145$) were those that participated in the North American Survey (NAS) [126], a retrospective natural history cohort with validated cancer diagnoses. The age-specific hazard of SCC was 4.4-fold higher and occurred at a younger age in transplanted patients (18 vs. 33 years; $p = 0.004$). However, the risk of cancer in transplanted FA patients was 33-fold higher in those with a history of acute GVHD and infinitely higher in those with chronic GVHD. Once diagnosed with SCC, survival was uniformly poor regardless of prior treatment. Similar results were observed in an independent analysis of the German Fanconi Anemia Registry ($n = 181$ FA patients). Rosenberg et al. [129] found that patients with FA were at an extraordinary risk of cancer with observed to expected ratios of 26 for all solid tumors. However, when focused on individual solid tumors, the observed-to-expected ratios were 6281 for esophageal, 2411 for vulvar, and 240 for head and neck cancers. Moreover, the risk of solid tumor was even higher after HCT (3.8-fold).

Based on these observations, there are several major conclusions: (i) the risk of solid tumor is high in FA patients regardless of transplant; (ii) in transplant and non-transplant patients with FA, solid tumors are very rare in the first decade of life, except in FA patients with biallelic mutations in FANCD1/BRCA2 and FANCN/PALB2, and the peak incidence is in the third and fourth decades; (iii) HCT is associated with an increased incidence of solid tumor and occurs at an earlier time point relative to that observed in non-transplant patients; and (iv) the increased incidence after HCT is driven by GVHD.

To address the role of HCT further, we evaluated the clinical dataset of 185 FA patients transplanted at the University of Minnesota between 1976 and 2015. As we had focused on reducing the risk of GVHD early on (1994) either by incorporating T-cell depletion in all marrow recipients or using umbilical cord blood if a closely HLA-matched donor was not available, it is possible that cancer risk was low. With a maximum follow-up of 15.4 years and 79 patients alive >3 years after HCT, six cancers were observed (three SCC of the tongue, larynx, and salivary gland; one adenocarcinoma of the lung). The interval from transplant to solid tumor diagnosis was 0.9 to 15.5 years, respectively. The age at diagnosis was 20.5, 32.3, 41.0, and 42.1 years. At 45 years of life, the incidence of solid tumor was 14% (95% CI, 2–14%), lower than expected based on prior report. Together these data suggest that higher risk of solid tumors previously observed in FA patients undergoing HCT may be driven by GVHD. Of note is the poor overall survival after treatment of FA patients with head and neck SCC, since standard treatment for SCC incorporates surgery in combination with radiotherapy and chemotherapy with DNA cross-linking drugs. In addition to severe mucositis which is difficult to manage in this population, pancytopenia is common in FA patients developing SCC without HCT and may lead to further complications, particularly bleeding and infection [130].

Why this is significant to the transplant team? All long-term survivors of FA with or without a history of allogeneic HCT are at high risk of cancer. Rigorous surveillance and cancer prevention programs are critical for the survival of FA patients particularly after the age of 20 years. However, new data suggest that SCC may not be higher in FA patients treated with allogeneic HCT as long as GVHD is prevented regardless of the conditioning (TBI vs. chemotherapy only) employed. Therefore, [in FA patients without leukemia], treatment plans that do not incorporate appropriate strategies for in vivo or ex vivo T-cell depletion are not acceptable based on the consequent high risk of cancer.

Genetic counseling

All patients and their families should receive genetic counseling from a professional knowledgeable about FA and the unique issues specific to this patient population. The consultation should include a discussion of the mode of inheritance, the phenotypic consequences of FA, genetic testing options, and reproductive counseling as well as obtaining a detailed health and family history with a particularly focus on dysmorphology, blood disorders, and types of cancers. Once diagnosed with FA, additional molecular studies are critical for the comprehensive clinical management of the patient. For some, it is essential for genetic counseling and carrier screening to be made available to extended family members; for others, previously identified genotype–phenotype correlations may help predict the clinical course. In general, the genetic counselor may choose the type of molecular test based on the history and specific needs of the family. For example, if there is a strong cancer history in the family or cancer in the patient at an early age, FAND1/BRCA2 (Myriad) or FANCN/PALP2 testing may be appropriate. However, in some cases, as in patients of Ashkenazi Jewish decent, mutation analysis may be targeted for FANCC (c.456+4A>C). For other cases, the conventional approach until recently has been complementation group analysis (i.e., correction of the DEB/MMC sensitivity by transfection of cDNA of one of the 17 FA genes) followed by gene-specific sequencing. However, large deletions or duplications can complicate molecular diagnosis. Next generation sequencing is becoming more widely available. Importantly, radical changes in methodology have recently made it possible to identify the complementation group and both mutations for FA patients in a faster and more economical way. Whole exome sequencing can now be used to detect mutations in a single study. Still, this approach is faced with pitfalls, such as failure to identify mutations that are intronic or in gene regulatory regions not covered by current exomic technologies. Furthermore, *FANCD2* mutations are complicated by the presence of two pseudogenes for *FANCD2.* Still, additional new technology such as RNA-seq, (sequencing-based RNA analysis) and aCGH (array-comparative genomic hybridization) has been shown to allow identification of both mutant alleles without prior complementation studies in all FA patients tested (Auerbach, unpublished data). The genetic counselor will help establish which tests are most appropriate for a specific patient and family and will inform patients, parents, and their extended family members of their cancer risk should mutations be identified in downstream factors, most notably FANCD1/BRCA2 and FANCN/PALB2. For the practitioner, the list of available CLIA-licensed US and non-US testing facilities can be found in the GeneTests™ Laboratory Directory (https://www.genetests.org/).

Prenatal testing

For nearly all couples at risk of having children with FA (likely because they have already had one child with the disease), reproductive counseling is mandatory. At a minimum, couples need to be aware of the risks of FA in future children so that they can make an informed decision about birth control, prenatal testing, and use of various assisted reproduction techniques, including embryo screening with PGD [131]. Chromosomal testing may be applied to the study of fetal cells obtained by chorionic villus sampling (CVS), amniocentesis, or percutaneous umbilical blood sampling. However, it should be noted that recently Fan et al. reported [132] that it is possible to non-invasively sequence the entire prenatal genome using a maternal blood sample obtained in the first trimester of gestation. Research is now ongoing to screen for mutations in single gene disorders using similar shotgun sequencing of fetal DNA in maternal plasma. In the not-too-distant future, it will likely be possible to use such techniques to prenatally diagnose FA in cases where the parental mutations are known.

Assisted reproduction

If the couple is interested in the use of IVF with PGD for the purpose of avoiding the implantation of affected embryos, identification of the mutated FA gene is required for embryo genetic screening. However, there is the additional possibility that couples can also screen for a specific HLA type, in the circumstance that an HLA-matched, unaffected child is desired to serve as an allogeneic HSC donor. In these circumstances, it is important to identify a team experienced in IVF that understands the specific goals of the couple and that can provide reliable estimates of the chance for success. Importantly, the IVF procedure does not have to be performed at the location of the PGD team or transplant center. As with IVF for infertile couples, the procedure requires daily injections to stimulate follicle development and maturation. After retrieval, each ovum is fertilized. After 2–3 days, at the 8–10 cell stage, a single cell is removed and tested for FA and HLA. Embryos that are free of disease and HLA-identical (if appropriate) are identified and implanted at that time or at a future time, depending upon the desire of the family.

Due to the risk of error inherent in testing a single cell prior to embryo transfer, CVS or amniocentesis should be strongly encouraged to confirm that the fetus is unaffected and HLA-identical if desired. In the latter setting, prior to delivery, arrangements are made for collection and shipment of the UCB from the HLA-identical healthy sibling along with maternal blood for infectious disease testing to the transplant center. Prior to HCT the newborn donor is evaluated for FA and HLA a third time, due to the critical importance of these results to the child being transplanted. To summarize, this represents the general approach toward the combined use of IVF and PGD and then UCB collection for interested couples at high risk of having a child with FA. For the practitioner, it is important to know the procedural steps at least generally and the potential ethical implications [133,134]. While the breadth of applicability remains to be identified and as the debate regarding the use of IVF and PGD to select embryos with desirable characteristics continues, it is clear from the number of referrals that there is increasing interest in the use of these technologies. Transplant physicians need to be intimately involved from the outset, not only to coordinate care but also to assess whether the patient's condition will permit sufficient time for the delivery of the healthy HLA genotypic-identical sibling donor.

Future directions

Improved understanding of the function of the FA genes has already profoundly affected our understanding of apoptosis, DNA repair, and regulation of normal hematopoiesis. Defects in the FA pathway are known to occur in somatic cells of non-FA patients, causing a variety of cancers, such as breast and ovarian cancer [30,135–138]. In addition to searching for strategies that would repair the FA defect in hematopoietic cells and eliminate the need for allogeneic HCT, others are searching for ways to induce a defect in the FA pathway that would enhance chemoradiotherapy sensitivity in otherwise highly lethal cancers. With regard to transplant physicians, the focus will continue to be close surveillance for marrow failure and cancer and development of even safer transplant strategies (e.g., use of ex vivo expansion culture of UCB HSC or reduced exposure to cytotoxic agents).

Gene therapy

The possibility of using gene transfer methods for correcting genetic diseases of HSCs has received much attention. The availability of FA genes has spurred considerable interest in the development of gene therapy for this disease for two reasons: (i) relatively few FA patients have HLA genotypic-identical HSC donors; and (ii) the risks of morbidity and mortality after unrelated donor HCT in specific high-risk subpopulations are substantial. One potential alternative to HCT could be the infusion of genetically corrected HSCs.

While there have been numerous reports [139–144] demonstrating that recombinant virus transduction of FA cDNA into FA $CD34^+$ hematopoietic progenitor cells improves clonogenic potential with phenotypic correction of CFC in vitro, as shown by resistance to MMC-induced cell death, loss of susceptibility to chromosomal breakage and restoration of cell cycle kinetics, clinical trials of gene transfer have not yet been successful. Liu et al. [140] reported the results on the first clinical trial in FA, specifically testing gene-corrected autologous HSC in patients with mutations in *FANCC.* In this study, a retroviral vector containing the *FANCC* and neomycin resistance coding sequences was used. After infusion, *FANCC* transgene was present transiently in the peripheral blood and BM. Function of the *FANCC* transgene was suggested by a marked increase in hematopoietic CFC, including colonies in the presence of MMC, after successive infusions of transduced cells. Despite a growth advantage in vitro, there was only transient evidence of gene-corrected HSCs amplification in vivo.

Since these early attempts, a great deal remains to be learned regarding gene therapy in the treatment of FA [142,145–147]. Improvements in HSC mobilization, gene transduction efficacy, long-term gene expression and safety have been made. More recent work suggests that lentiviral vectors may be a strategy for efficient gene correction of quiescent HSCs. While gene therapy is not yet proven in the context of FA, FA is a particularly attractive candidate disease for such a therapeutic approach owing to an inherent selective survival advantage of the corrected HSC. Trials with genetically modified autologous HSC for FA are in the pipeline. While of considerable interest scientifically, paucity of HSC targets, risk of accumulated chromosomal aberrations, and high success rates in recipients of allogeneic HCT regardless of donor type have slowed progress in the field of gene therapy for FA. The optimal candidate for testing the safety of HSC gene correction may be one who has a risk factor that effectively eliminates transplant as a reasonable option (e.g., poor renal function, history of solid tumor). While older age may be a high risk factor for transplant, older age is also associated with high risk of chromosomal abnormalities, MDS, and paucity of HSC. However, new strategies of HSC expansion are becoming available that could catapult the hope of gene therapy for FA in the not-too-distant future.

Stem cells and tissue repair

Embryonic stem cells are pluripotent cells derived from the inner cell mass of the blastocyst that can be propogated indefinitely in the undifferentiated state or differentiated into many cell lineages at least in vivo. More recently, inducible pluripotent stem cells (iPSC) have also been isolated from skin fibroblasts obtained from FA patients [148,149]. Irrespective of their origin, stem cells hold great promise for the treatment of many degenerative and inherited diseases. In the setting of FA, stem cells could be used as a strategy to enhance tissue repair after chemoradiotherapy, as intense local injury could itself be debilitating and life-threatening, such as that for the treatment of solid tumors. Alternatively, genetically corrected stem cells from the FA patient him/herself could be used as source of HSCs. Gene correction of patient-specific iPSC followed by differentiation into HSC is being explored as a particularly attractive strategy for treating the bone marrow failure common to most patients with FA.

Conclusion

FA is one of the truly amazing success stories in the field of allogeneic HCT. Once considered the “last resort” because of the extremely high risk of severe treatment-related toxicity, transplant is generally considered the first-line treatment for the FA patient with bone marrow failure. However, the hematologist, geneticist, oncologist, or other subspecialist making the diagnosis of FA (regardless of the patient’s age) should refer the patient to a FA Comprehensive Treatment Center as early as possible and not just at the time that marrow transplant may be needed. Such centers will provide a comprehensive evaluation focused on the unique issues of this disease from diagnostics (e.g., complementation group assignment and mutation analysis) and reproductive counseling (e.g., embryo selection, prenatal testing) to treatments and preventative care for specific organ dysfunctions (including marrow failure) and late effects (e.g., cancers, short stature, and endocrinopathies).

All patients with FA should be followed routinely by a hematologist experienced with the unique issues surrounding this disease, even prior to the onset of marrow failure when possible. Annual marrow examinations should begin early, particularly in patients with mutations in FANCD1/BRCA2. Enhanced surveillance with annual marrow examinations that include a comprehensive cytogenetic evaluation reduces the risk of an undiagnosed disease progression toward advanced MDS and leukemia. For general purposes, a surveillance plan and treatment algorithm are proposed, which will reflect those used by experts in the field (Figure 76.14). Expectedly, general approaches cannot reflect the specific issues for specific patients with FA, which may necessitate alternative considerations. However, at the time of FA diagnosis in one child, it is critical that all siblings of the proband be tested for FA regardless of age, phenotype, and HLA type. In those circumstances where severe cytopenia already exists (or is impending), a donor search should be activated urgently in order to move to transplant prior to the need for transfusions or development of opportunistic infections. While transplant is not a good option for some patients because of preexisting comorbidities (e.g., infection, cancer) or lack of a suitable donor, this is unusual. For the majority who are good transplant candidates, allogeneic HCT today, whether from an HLA-matched sibling or unrelated donor, is offered with a high expectation of success.

SECTION 7 Complications of Hematopoietic Cell Transplantation

CHAPTER 77

Mechanisms and Treatment of Graft Failure

Robert Lowsky[1] **and Hans Messner**[2]

Introduction

The ability of hematopoietic stem cells (HSCs) to circulate and to migrate from marrow to blood and back is an intrinsic aspect of the hematopoietic system. The biological role and physiologic significance of HSC circulation remains unclear, yet it is this trafficking that results in stable hematopoietic cell engraftment and forms the basic requirement for successful hematopoietic cell transplantation (HCT) in the treatment of hematologic and non-hematologic diseases. The failure to achieve sustained engraftment following HCT is associated with considerable morbidity and mortality, most notably infections and hemorrhagic complications due to marrow hypoplasia, and/or relapse of disease. This chapter reviews the clinical aspects associated with, and treatment of, graft failure (GF).

Overview of trafficking, homing, and engraftment of HSCs

The restoration of adequate blood cell production after HCT requires a series of balanced interactions between the infused HSC and its complex supporting marrow microenvironment.

Following HSC infusion, the cells initially adhere loosely to the vascular endothelium in the bone marrow with sufficient strength to overcome the hemodynamic shear forces of blood flow [1]. The predominant HSC cell surface molecules that mediate initial tethering are the selectin ligands, P-selectin glycoprotein ligand-1 (PSGL-1) and the hematopoietic cell L-/E-selectin ligand (HCELL), that interact with endothelial E- and P-selectin [2,3]. Thereafter, firm HSC adhesion is mediated by activation of the HSC cell surface integrin superfamily, principally VLA-4, α4β7, the α6 integrins, and LFA-1, that interact with endothelial immunoglobulin (Ig) superfamily receptors (e.g. VCAM-1), and the hyaluronate receptor CD44 [4,5]. HSCs null for cell surface α and β integrins do not adhere firmly to the endothelial surface, and are unable to home to the bone marrow (BM) niche even though they proliferate and differentiate normally in fetal liver [6,7]. Following firm adherence, transendothelial movement and homing to hematopoietic niches located within the inner endosteal surface of the bone are regulated by a gradient of extracellular matrix-bound SDF-1 (also known as CXCL12) binding to the CXCR4 receptor on HSCs [8]. Other potent HSC chemoattractants include gradients of the bioactive sphingophospholipids sphingosine-1 phosphate (S1P) and ceramide-1 phosphate (C1P) [9,10]. Following successful homing, adhesion of the HSC to its specific niche is mediated by a complex of many cell types, including mesenchymal stromal cells (MSCs) and parathyroid hormone (PTH)-receptor-bearing osteoblasts [11,12], in conjunction with a network of interacting marrow sinusoidal endothelial cells, facilitator T-cell subpopulations, adipocytes, and fibroblasts [13–15]. Successful HSC homing, adhesion, and engraftment may be compromised if the HSC, or its marrow niche, was previously damaged, possibly from prior chemotherapy and/or irradiation that the patient received. In the case of allogeneic HCT, the process is further complicated by immune-mediated host-versus-graft (HVG) and graft-versus-host (GVH) reactions. Given the intricacy of HSC trafficking from infusion to engraftment in its marrow niche, and the subsequent control of its self-renewal and differentiation, it is surprising that clinical HCT, in general, has a relatively low rate of GF.

Definitions

Graft failure is defined as the lack of hematopoietic cell engraftment following autologous and allogeneic HCT. Its criteria are predominantly operational, and the decades-old definitions of GF persist today. GF is divided into primary (early) and secondary (late) phases (Table 77.1).

Primary graft failure

Primary GF was defined as the failure to surpass a threshold absolute neutrophil count (ANC) of $0.5 \times 10^9/L$ by day 28 post-graft infusion, or $0.1 \times 10^9/L$ by day 21 [16–19]. The day of myeloid engraftment was assigned as the first of three consecutive days on which the ANC exceeded the targeted threshold. The day of platelet recovery was defined as the first day of a platelet count of at least 20, 50, or $100 \times 10^9/L$, sustained for 3 days without transfusion in the previous 7 days [16–19]. Platelet recovery was often delayed compared with myeloid recovery, or sometimes not achieved at all, especially if a higher platelet value ($100 \times 10^9/L$) was used as the threshold. The Center for International Blood and Marrow Transplant Research (CIBMTR) collects data regarding the number of days to count recovery using an ANC threshold of $\geq 0.5 \times 10^9/L$ and a platelet count $\geq 20 \times 10^9/L$. A hemoglobin level of ≥8…g/dL without transfusion support is an accepted threshold for red cell engraftment [20]. An isolated cytopenia does not necessarily invoke

Table 77.1 Definition of graft failure and poor graft function

Transplant type	GF type	Criteria	Notes
Graft failure, autologous and full-dose allogeneic HCT	Primary	ANC <0.5 × 10^9/L by day +28, with Hb ≤8…g/dL, platelet count <20 × 10^9/L and continued transfusion support	BM biopsy confirms absent hematopoiesis Day +28 is relative to the cell infusion date
	Secondary	ANC <0.5 × 10^9/L after initial engraftment, unrelated to infection, medication, or disease progression with red cell and platelet transfusion support	BM biopsy confirms absent hematopoiesis For date of onset, use first date ANC <0.5 × 10^9/L of 3 consecutive tests
Graft failure, RIC allogeneic HCT	Primary	(i) ANC <0.5 × 10^9/L by day +28, and assay confirming ≥5% donor type cells	BM biopsy may or may not confirm absent hematopoiesis
		(ii) Failure to surpass the 5% donor type threshold, even if essentially normal blood counts	Assay to confirm the absence or presence of donor cells
	Secondary	(i) ANC <0.5 × 10^9/L after initial engraftment, continued transfusion support and assay to confirm > 5% donor type cells	BM biopsy may or may not confirm absent hematopoiesis
		(ii) Loss of donor hematopoiesis to <5% irrespective blood counts	Assay to confirm the absence or presence of donor cells
Poor graft function		Requires two or three cytopenic lines (Hb <10…g/dL, ANC <1.0 × 10^9/L, platelet count <30 × 10^9/L) for >2 consecutive weeks beyond day +28, without transfusion support	Criteria for GF not met In allogeneic HCT requires assay to confirm presence of donor cells. A $CD34^+$ selected cell boost may be considered in poor graft function following HCT

GF, as this may represent a transitory phenomenon related to a medication, viral infection, a lineage-specific immune-mediated cytopenia, or graft-versus-host disease (GVHD).

Secondary or late graft failure

Patients who satisfied the criteria for initial engraftment but subsequently developed loss of a previously functioning graft defined by at least two lines of cytopenia (i.e. ANC ≥0.5 × 10^9/L on three laboratory values with subsequent decline to < 0.5 × 10^9/L for three or more laboratory values, and a platelet count that achieved threshold with subsequent decline to <20 × 10^9/L) were considered to have late or secondary GF [17,18]. Late GF is a phenomenon more often associated with allogeneic HCT than with autologous transplantation [18]. Some possible causes of late GF include graft rejection related to residual host immunity, progressive disease for which the patient was transplanted, low donor cell yield, medication side effect, infection, or GVHD.

Graft rejection and poor graft function

The term graft rejection refers to immune-mediated rejection of the donor allograft by residual host effector cells that occur because of genetic disparity between the recipient and the donor. Therefore, graft rejection is relevant to allogeneic HCT but not autologous or syngeneic HCT. Primary graft rejection is the absence of donor hematopoiesis within the first month after transplant, and late rejection is defined as a loss of donor cells after their initial graft function [19]. The determination of graft rejection requires analysis of the blood or marrow for chimerism to confirm the absence of, or loss of, donor hematopoietic cells. Graft rejection is a cause of GF. In contrast to graft rejection, the term poor graft function describes the failure to achieve adequate blood counts following allogeneic HCT, in the presence of complete or near complete donor hematopoietic cell chimerism [21].

Mixed chimerism following allogeneic HCT

Full-dose conditioning

The initial studies of chimerism were performed in allogeneic transplant recipients with hematologic malignancies who received full-dose conditioning and unmanipulated donor grafts. These patients achieved complete (100%) donor hematopoietic cell chimerism as a result of the intensity of the transplant conditioning, and the T cells in the graft contributed to graft-versus-lympho-hematopoietic reactions. It is reasonable to forgo chimerism testing in patients who have achieved complete blood count recovery after HCT and who received unmanipulated grafts following conventional full-dose conditioning and standard GVHD prophylaxis.

Reduced-intensity conditioning

It is well established that reduced-intensity conditioning (RIC) for allogeneic HCT is associated with incomplete eradication of host hematopoietic elements [22]. As a consequence, a significant percentage of patients have multi-lineage mixed donor–recipient hematopoietic cell chimerism extending at times for months after transplantation. Primary engraftment following RIC is defined by achieving the neutrophil, platelet, and hemoglobin thresholds cited above, yet in addition, attainment of ≥5% donor T ($CD3^+$) cells is required [17]. Even in the setting of complete blood count recovery, a failure to surpass the 5% donor type threshold is considered primary GF, and secondary GF is reserved for cases that initially surpass the 5% threshold but subsequently fall below it. Full or complete chimerism generally refers to 95–100% replacement of host by donor hematopoiesis, although most assays are semiquantitative and small percentages (<5%) of host cells may be undetected. Mixed chimerism indicates the presence of both donor and recipient cells, often considered between 5 and 95% donor type [17]. The term split chimerism is used when one or more lineage is derived wholly from the donor, and one or more lineage is derived from the host. There remains a lack of consensus regarding the use of these terms, and the thresholds that define complete and mixed chimerism. Similarly, the assays to assess chimerism are not standardized, and it is uncertain whether blood or marrow and lineage selection should be part of the analysis. Importantly, the relationships between persistent mixed chimerism, the risk of GF, and disease relapse is imperfect, and needs further study. It seems reasonable that if the intensity of the transplant conditioning is altered, new GVHD regimens are being studied, or if there is graft manipulation, measurement of chimerism is important to evaluate the effects of the change in the ability to obtain complete multi-lineage donor cell engraftment.

Incidence of graft failure

The reported incidence of GF varies, in part because the consequences associated with GF (i.e. morbidity and mortality due to infection or hemorrhage) are reported, and not GF itself.

To estimate the incidence of GF following autologous HCT, it is reasonable to consider that in most centers the 100-day non-relapse mortality (NRM) is <10%, of which only a small subset can be attributed to GF. A surrogate marker for estimating the incidence of

GF following autologous HCT is the requirement for hematopoietic cell rescue using a back-up product. In a single-center study of 300 consecutive patients who underwent high-dose therapy followed by autologous hematopoietic cell rescue between 1980 and 1997, 14 (4.7%) patients required rescue with their back-up product due to primary ($n = 12$) and late ($n = 2$) GF [23]. The risk factors for GF in this study were the use of BM, a diagnosis of acute myeloid leukemia (AML), $CD34^+$ selection, and ex vivo cytokine-expanded peripheral blood mononuclear cells (PBMCs) collected by apheresis. Given that these risks factors are present in a minority of autologous transplant recipients, a more reasonable estimate of the incidence of GF for the majority of patients undergoing autologous HCT is probably between 1 and 3%.

The incidence of GF is higher in allogeneic transplant recipients, especially if the patient receives an human leukocyte antigen (HLA)-mismatched or T-cell-depleted graft, or if a single unit umbilical cord blood (UCB) transplant was performed. Depending on the specific particulars of the transplant, the risk of GF was reported to occur in 2–20% of allogeneic HCT recipients [24–26]. Some transplant centers opt to store autologous marrow or blood-derived hematopoietic progenitor cells for patients undergoing allogeneic HCT [23,24,26]. Ninety-four of 306 (31%) European centers completed questionnaires regarding their policy of storing autologous back-up cells for allogeneic HCT recipients, and just over half of the centers had such a policy [26]. The most common indications for an autologous back-up harvest were the use of a matched or mismatched unrelated donor or UCB. Some North American transplant centers also store autologous back-up cells for salvage purposes [24].

Causes of graft failure

A list of contributing risk factors for GF is given in Table 77.2.

Table 77.2 Risk factors for graft failure

Quantitative factors:
- Low $CD34^+$ cell yield
- Presence of splenomegaly
- Graft source (cord blood > bone marrow> mobilized blood)

Qualitative HSCs and marrow niche related factors:
- Extensive pre-transplantation chemotherapy and/or irradiation
- Iron overload
- Marrow fibrosis
- Disease status
  - >1–2 years from date of initial diagnosis
  - Marrow involvement with disease
  - Refractory disease
- Disease category
  - Inherited disease of erythropoiesis (SCD and thalassemia)
  - Severe acquired aplastic anemia
  - MDSs and CMNs
- Advanced recipient and/or donor age
- Storage techniques and expertise

Immunologic:
- Donor and recipient HLA disparity
- Presence of pre-transplantation DSAs
- Graft manipulation (i.e. TCD or $CD34^+$ cell selection)
- Extensive pre-transplantation transfusion history
- Post-transplantation immune suppression regimen
- Type and intensity of transplantation conditioning
- Presence of acute or chronic GVHD
- Viral infections (HHV-6, parvovirus, CMV)

CMNs, chronic myeloid neoplasms; CMV, cytomegalovirus; DSAs, donor-specific antibodies; HSCs, hematopoietic stem cells; MDSs, myelodysplastic syndromes; SCD, sickle cell disease; TCD, T-cell-depleted.

Immune-mediated graft rejection

Donor contribution

It is well established that donor T cells in the allograft promote hematopoietic engraftment as depletion of T-lymphocytes from the marrow graft before transplantation by any of a number of means was associated with a substantial increase in the occurrence of graft rejection [27–29].

The mechanism by which donor T cells inhibit graft rejection remains poorly defined. In murine transplantation models, donor $CD8^+$ T cells were reported to be much more potent facilitators of short- and long-term engraftment than $CD4^+$ T cells [30,31]. It is thought that donor T cells directly suppress, or eliminate, host effector cell populations. In a murine model of transplantation, BM engraftment across MHC class I or II barriers required donor $CD8^+$ T cells with intact perforin pathways to achieve sustained engraftment and prevent graft rejection [30]. Another possibility is that donor T cells provide cytokines that influence the ability of donor hematopoietic progenitor cells to home to the marrow niche or augment their proliferation, despite the fact that host effector cells may not have been suppressed. Secretion of granulocyte–macrophage colony-stimulating factor (GM-CSF) by donor-derived alloreactive T cells augmented HSC proliferation [32].

Efforts to characterize cell populations in the donor graft that facilitate engraftment without causing GVHD remain an area of active research. In most rodent models of bone marrow transplantation (BMT), unfractionated $CD4^+$ T cells do not possess efficient facilitating potential to support donor hematopoietic cell engraftment whereas unfractionated $CD8^+$ T cells do [30]. In a preclinical murine model of BMT, the infusion of donor-derived $CD8^+$ memory T cells at day +16 after transplantation converted MHC major and minor mismatched recipients with mixed chimerism to full donor chimerism without the development of GVHD [33]. Other $CD8^+$ subpopulations, specifically $CD8^+CD3^+$ but negative for αβTCR and γδTCR, facilitated BM cell engraftment without provoking GVHD in an MHC-disparate mouse model of transplantation [34]. Additionally, a special class of antigen-presenting cells (APCs) that carry CD8, called veto cells, deliver an apoptotic signal to T cells that recognize them [35]. Although the nature of this signaling pathway is not yet defined, it was demonstrated in murine models of BMT that the transfer of donor-derived veto cells supported HSC engraftment through the inactivation and elimination of alloreactive host T cells [36]. The infusion of donor $CD4^+CD25^+$ regulatory T (Treg) cells in a murine model of RIC for BMT in MHC-mismatched strains facilitated engraftment of donor BM cells, suggesting that donor Treg cells may regulate HVG reactions [37]. A clearer understanding of the role of various donor T-cell populations, including Treg cells, veto cell populations, and costimulation signaling pathways, has the potential to reduce HVG reactions that underlie immune-mediated allograft rejection.

Host contribution

Preclinical studies established that the increased risk of graft rejection following the infusion of a T-cell-depleted (TCD) graft was due to enhanced susceptibility of the graft to regimen-resistant host immune cells that included host natural killer (NK) cells, natural killer T (NKT) cells, γδ TCR T cells, and conventional $CD4^+$ or $CD8^+$ T cells [38–41].

Host NK cells contribute to graft rejection

Over 40 years ago and using murine models of BMT, investigators showed that parental homozygous BM allografts were rejected by their heterozygous F1 hybrids in a non-MHC-dependent manner as a result of regimen-resistant host NK cells [38,42]. Pretreatment of the conditioned host with antibody directed against NK-cell-associated antigens abrogated graft rejection [43]. Additional evidence that NK cells alone can mediate BM cell rejection was observed in severe combined immunodeficiency syndrome (SCID) mice that lacked T and B cells but had normal NK-cell function, as these mice rejected BM cell allografts, even after lethal irradiation [44]. NK-cell-mediated BM graft rejection can be regulated by host and donor Treg cells. Using the F1 hybrid resistance model in which the parental BM graft was rejected solely on the basis of NK cells, the prior removal of host $CD4^+CD25^+$ Treg cells significantly enhanced NK-cell-mediated BM rejection [45]. In contrast, when the BM graft was supplemented with donor Treg cells, NK-cell-mediated BM graft rejection was abrogated [45]. In clinical HCT, firm evidence of NK-cell-mediated resistance to engraftment is lacking, due in part to the lack of tests that discern T-cell- from NK-cell-mediated resistance. Human NK cells are highly sensitive to cyclophosphamide, and are suppressed by the use of post-transplantation immune suppression medication [46]. It is also possible that the quantity of hematopoietic cells infused in clinical transplantation may be sufficient to override resistance by host NK cells. In a murine model of BMT, NK-cell-mediated graft rejection increased as the intensity of transplant conditioning was reduced [47]. It is tempting to speculate that NK cells may play a more significant role in graft rejection following RIC regimens in humans.

Host T cells contribute to graft rejection

It is presumed that a dominant cell type mediating allogeneic BM cell rejection in non-sensitized recipients is regimen-resistant $CD8^+$ effector cytolic T cells that induce donor hematopoietic cytotoxicity primarily through Fas–Fas ligand (FasL)- and perforin-dependent pathways [48–50]. However, disruption of these two major cytotoxic pathways did not completely eliminate resistance to BM cell engraftment [48–50]. Furthermore, the elimination of any one selected cytokine in recipient mice, including tumor necrosis factor-alpha (TNF-α), transforming growth factor-beta (TGF-β) and polarizing T-helper (TH)1 and TH2 cytokines, did not reduce the resistance to allogeneic BM cell engraftment [48]. Based on the aggregate literature, it is reasonable to presume that redundant host effector T-cell pathways help mediate BM cell rejection. Understanding the pathways of resistance mediated by host T-cell populations after high-dose and reduced-intensity conditioning regimens will be important for the development of effective strategies that lead to stable engraftment after allogeneic HCT.

It is reasonable to assume that BM cell rejection is faster in sensitized than non-sensitized recipients as there is no need for a T-cell effector induction phase. There is evidence that $CD44^{lo}$ naïve T cells are significantly more sensitive to graded doses of total body irradiation (TBI) than are $CD44^{hi}$ memory T cells and NKT cells [51]. In a murine model of BMT, memory T cells following immunization to major and minor mismatched alloantigens persisted after myeloablative TBI whereas naïve T cells did not, and prevented BM cell engraftment [51]. In clinical HCT, in which almost all donors are HLA matched with recipients, multiple pre-transplant recipient blood transfusions can result in an increased risk of graft rejection [19]. This is presumed to be due to white blood cells (WBCs) in the transfusions that express minor histocompatibility antigens (mHAs) and immunize recipients to cross-reactive mHAs in the donor graft. It is reasonable to consider that in humans, memory T cells directed to minor alloantigens in patients exposed to mHAs over a long period of time are also radioresistant, and can contribute to graft rejection.

Host B sells contribute to graft rejection

Antibody-mediated BM rejection either by antibody-dependent cell-mediated cytotoxicity or complement-mediated cytotoxicity has been described [52]. Preformed antibody present at the time of transplantation is not readily controlled with conventional standard conditioning regimens or with post-transplantation immune suppression medication. Strategies such as plasmapheresis, high-dose intravenous immunoglobulin, splenectomy, and immunoadsoption used in solid organ transplantation to eliminate antibody-mediated rejection are generally not part of HCT conditioning regimens and consequently their effectiveness at mitigating graft rejection has not been formally evaluated. In a murine model of BMT, it was shown that a single priming against an MHC-disparate strain resulted in antibody-mediated BM cell rejection that was rapid (<3 hours), whereas T-cell-mediated BM rejection in non-primed mice took more than 6 days [41]. In this model, BM cell rejection in sensitized hosts was overcome using the combination of a high dose of donor BM cells, with high-dose immunoglobulin and T-cell-depleting antibodies to target host T cells that survive TBI conditioning [41]. Evidence of relevance in clinical transplantation was demonstrated when pre-transplantation sera samples from patients who received HLA-mismatched grafts and developed GF were compared with an appropriate HLA-mismatched engraftment case–control cohort. Among the 37 GF patients, 24% tested positive for donor-specific antibodies (DSAs) against HLA-A, -B, and/or -DP compared with only 1% of the 78 engraftment controls [53]. Another study confirmed donor-specific anti-HLA antibodies were associated with a high rate of graft rejection in patients undergoing haploidentical HCT [54]. The presence of DSAs may also be an important contributor to GF following UCB transplantation [55]. It is reasonable to evaluate routinely for the presence of DSA in recipients of HLA-mismatched donor grafts and to consider strategies to eliminate the potential impact on GF.

The contribution of B-cell-mediated BM graft rejection in histocompatible siblings is less clear, even in the setting of prior sensitization. In human transplantation, the presence of radioresistant anti-donor cytotoxic T-lymphocyte (CTL) populations sensitized to donor mHAs in individuals who had a prior transplant, or in patients with severe aplastic anemia (SAA) who were sensitized through repeated blood transfusions, was associated with high levels of graft rejection [56,57]. In contrast, rejection did not commonly occur in recipients with cross-match antibodies, and the panel reactive antibody test in SAA recipients did not predict graft outcomes [56,57].

Understanding how donor HSCs are recognized and resisted is a complex biologic question. From preclinical models, it is evident that a variety of host cell populations contribute to resistance and that their roles are influenced by multiple factors, including genetic disparity, prior sensitization, graft content, and recipient preparation. Similarly, there are populations of cells contained within the donor allograft that effect engraftment. The continued unraveling of how transplanted HSCs are targeted and suppressed will undoubtedly contribute to developing strategies that ensure successful engraftment, and reduce the risk of GF.

Histocompatibility antigens

Comparing studies that evaluated the impact of HLA compatibility with the risk of GF following allogeneic HCT is challenging. The main reason relates to the difficulty in assessing the true degree of incompatibility in earlier studies. Also, donor selection in early studies was often based on matching criteria for HLA-A, -B, or -DR, which might not reflect matching at HLA-C, -DP, or -DQ. Consider that in 205 patients who underwent transplantation from HLA-A, -B, -C, -DRB1, and -DQB1 molecularly matched unrelated donors, a single-allele HLA-DP mismatch was identified in 90 recipient donor pairs and a two-allele mismatch was determined in 60 pairs [58]; the effect of mismatch on GF was not evaluated in this study. The disconnect between earlier and recent studies is highlighted in that virtually all earlier studies reported that an increase in the degree of HLA mismatch was associated with an increased risk of GF for sibling and unrelated donor BM grafts [59–61]. However, this is not a consistent observation in recent studies; a National Marrow Donor Program (NMDP) report evaluated HLA-A, -B, -C, -DRB1, -DQB1, -DQA1, -DPB1, and -DPA1 alleles and showed no statistically significant difference in the risk of GF between 7/8 (either allele or antigen) and 8/8 matched unrelated donor recipient pairs [62]. In another study of 709 patients with hematologic malignancies who received unrelated donor grafts following RIC, allele level HLA typing was performed at HLA-A, -B, -C, and -DRB1, and the risk of GF was not increased in recipients of HLA-mismatched grafts compared with recipients of fully matched grafts [63]. In this study, the only significant risk for increased GF was the use of BM compared with peripheral blood progenitor cells (PBPCs). Also, in this latter study, GF was not associated with a higher mortality risk, because patients with GF received effective salvage therapies, such as a donor cell boost or a second transplant [63].

ABO match

ABO incompatibility between donor and recipients occurs in approximately 25% of HLA-matched allogeneic transplants. Incompatibility was defined as major when the recipient plasma had isohemagglutinin (ISO) against donor red blood cell (RBC) antigens and minor when the donor had ISO against recipient RBC antigens. Bidirectional ABO incompatibility occurred when combined features of major and minor incompatibility were present. In the majority of studies, ABO incompatibility had no influence on the kinetics of neutrophil and platelet recovery time or the risk of GF [63,64] but has been associated with pure red cell aplasia.

Additional factors that might influence graft failure risk

Age

It remains unclear whether patient and donor age impact the incidence of GF. In autologous transplantation, higher patient age adversely impacted the ability to mobilize a sufficient number of progenitor cells to support successful engraftment in patients with multiple myeloma, Hodgkin disease, and non-Hodgkin lymphoma (NHL) [65]. However, in other reports no difference was observed in the total number of $CD34^+$ cells collected from older and younger myeloma and lymphoma patients [66]. The use of a CXCR4 inhibitor, especially when combined with granulocyte colony-stimulating factor (G-CSF), generally overcomes a low $CD34^+$ cell yield [67].

In allogeneic HCT, higher donor age was significantly associated with lower circulating $CD34^+$ cell counts and lower $CD34^+$ cell yields following G-CSF mobilization [68]. The lack of prospective studies designed to evaluate if donor age impacts the risk of GF preclude firm conclusions. At the time of writing of this chapter, the NMDP accepts healthy unrelated donors in the 18–44 years age group in recognition that physician preference is a younger donor. Donors between 45 and 60 years of age who meet health guidelines can also join, following a required US$100 tax-deductible payment.

An emerging hypothesis is that we age through accumulated damage to our stem cells including HSCs, and that the damaged stem cells have diminished cell function, which, in the case of HCT, means a reduced capacity for hematopoietic reconstitution . HSC reserve and function were evaluated in older and younger mice, and stem-cell functional capacity was impaired in older mice, which led to a loss of proliferative potential and, ultimately, functional exhaustion [69]. In another murine model, the HSC population from older mice competed poorly with the HSC from younger mice in competitive long-term repopulation assays [70]. The lower engraftment potential from older mice was due, at least in part, to a defect in the ability of HSCs to home to the marrow niche, as direct BM injections negated some of the difference in competitive repopulation assays [70]. An unanswered question remains: do old stem cells transplanted into young patients impact the likelihood of achieving sustained engraftment?

Telomeres are non-coding regions of DNA that cap the ends of eukaryotic chromosomes to protect against the enzymatic breakdown of coding DNA and prevent fusion or other chromosomal aberrations [71]. Telomeres shorten 50–150 base pairs with each cell division in cells that do not express telomerase. The maintenance of telomere length by expression of telomerase postpones senescence and its constitutive expression is a general requirement for immortalization of cells [71]. Several studies involving adult and pediatric patients showed that following allogeneic HCT, the telomere lengths in the transplanted blood and marrow cells were 0.4–2…kb shorter than those of their respective donors and age-matched controls [72,73]. This degree of accelerated telomere loss was equivalent to 15–70 years of additional ageing. Two cases of late GF following high-dose allogeneic HCT were associated with significant telomere shortening in the donor hematopoietic cells compared with the donor's native cells [74]. In these cases, GF due to medication, infection, relapse, immune-mediated rejection, or GVHD was ruled out.

Taken together, the data suggest that transplantation using a marginal graft with a limited number of HSCs, or transplantation using partially damaged HSCs from older donors, or HSCs that may have short telomeres to start with for whatever the reason, can put high demands on their proliferative potential that may eventually result in exhaustion and subsequent GF. Given the increasing number of long-term survivors of HCT and the increasing age of recipients and donors, it is important to understand age-associated regulators of HSC function. It is conceivable that this knowledge may eventually be used as selection criteria to maintain better the integrity of the repopulating HSCs and reduce the risk of GF or other adverse outcomes.

Diagnosis

The risk of GF can depend on the underlying disease, yet it is difficult to draw firm conclusions because studies often combine patients with different stages of diseases, conditioning regimens, graft source and content, and other variables that are likely important in contributing to GF.

Aplastic anemia

In general, patients with SAA have a GF rate that is higher than observed in acute leukemia [19]. This is in part because after transplantation these patients may have retained the immune-mediated recognition of stem-cell antigens that formed the targets of the pathophysiology of the disease, and they may have been sensitized before transplantation to allogeneic mHA targets that can result in graft rejection. Transplantation early in the disease course and before sensitization to histocompatibility antigens reduced the GF rate in patients with SAA, yet it is likely that only a minority of patients do not receive transfusions prior to transplantation [19].

Myeloid disorders

The GF rate in pediatric and adult patients undergoing allogeneic full-dose or RIC HCT for myelodysplastic syndromes (MDSs) and chronic myeloid neoplasms (CMNs) is increased compared with patients with acute leukemia [75–80]. Some investigators recognized that patients with MDSs and CMNs, especially myelofibrosis (MF), have a prolonged blood count recovery time, and instead considered GF as cytopenia beyond day 50 after transplantation [81]. Patients with MDSs, chronic myelogenous leukemia (CML), and other CMNs often have not received pre-transplantation intensive chemotherapy, and therefore may resist donor cell engraftment due to the presence of residual intact host effector cells. Patients with MDSs and CMNs may also have a defective marrow microenvironment that increases resistance to donor cell engraftment [78,79]. It is possible that therapy specifically targeting the underlying disease (i.e. cytadine analogs for MDSs or tyrosine kinase inhibitors for CML) given post-transplantation, or more intensive immune suppression, before or immediately after HCT, might facilitate engraftment, particularly if RIC is being considered in patients with CML, MDSs and MF.

The presence of massive splenomegaly in patients with CMNs is considered a risk factor for GF or delayed engraftment following allogeneic HCT [82]. In some patients, splenectomy, splenic irradiation, or treatment with JAK3 inhibitors is considered prior to allogeneic HCT as an intervention to improve the likelihood of successful donor cell engraftment, although this remains a debatable perspective [82,83].

Hemoglobinopathies

Thalassemia is associated with a relatively high GF rate, and risk factors include hepatomegaly (>2…cm below the costal margin), the presence of portal fibrosis in the pre-transplant liver biopsy, and the quality of iron chelation during the years before transplant (considered good if regular deferoxamine therapy was initiated within 18 months of the first transfusion and administered continuously for 8–10 hours for at least 5 days per week) [84,85]. The incidence of GF following high-dose conditioning and BMT from HLA-matched sibling donors was 10% for patients with no risk factors, compared with 25% for patients with all three risk factors [86]. The experience in patients with sickle cell disease (SCD) is similar; CIBMTR data collected in a 13-year period from 1989 to 2002 confirmed that nine of 67 (15%) recipients of HLA-matched related BM grafts developed GF following high-dose busulfan–cyclophosphamide (BU–CY) conditioning [87]. More recently, RIC containing alemtuzumab, or antithymocyte globulin (ATG) with post-transplantation CY, established persistent mixed chimerism in the majority of SCD patients who received grafts from HLA-matched sibling donors, and reported a GF rate of just under 10% [88,89]. This regimen when applied to haploidentical donors resulted in a GF rate of just over 40% [89].

Disease status

Many studies have demonstrated that in allogeneic HCT recipients with AML, CML, MDSs, and SAA, a long interval from diagnosis to transplant was associated with an increased risk of mortality, due in part to increased GF [19,59,76,80]. The increased GF rate may be the consequence of previous intensive treatments that damaged the marrow microenvironment, and/or excessive prior transfusion history resulting in HLA sensitization. The difficulty in achieving sustained engraftment in patients with advanced-stage disease may also relate to the kinetics of rapid tumor regrowth after transplantation.

Previous treatment

Experimental and clinical data showed that exposure to cytotoxic agents and radiation therapy damaged hematopoietic progenitors and impaired their repopulating ability. Animal studies confirmed melphalan, 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU), and BU significantly reduced the repopulating capacity of BM progenitor cells compared with CY, etoposide, and cytosine arabinoside (Ara-C) [90]. Salvage regimens containing agents that potentially affect progenitor cell function might compromise engraftment following autologous HCT. In keeping with these preclinical studies, exposure to a salvage regimen that contained BCNU or melphalan was shown to be a significant factor that adversely affected progenitor cell yield and performance of the graft, and was associated with an increased risk of GF following autologous HCT [91]. Dose intensity may also be important as patients who received higher dose cyclophosphamide, hydroxydaunomycin (doxorubicin), vincristine, and prednisone (CHOP) had a significantly prolonged time to engraftment following autologous HCT than patients who received standard-dose CHOP [92]. Lenalidomide used to treat patients with myeloma prior to autologous harvest decreased the number of $CD34^+$ cells collected, and increased the number of aphereses needed to obtain adequate cell numbers for transplantation compared with myeloma patients who received other therapies [93]. The negative impact of lenalidomide on $CD34^+$ cell collections was overcome when patients were mobilized with chemotherapy combined with G-CSF [94].

The evaluation of a bone marrow aspirate for abnormal cytogenetic clones that may have developed from prior chemotherapy therapy in patients planned for autologous harvest is important. Infusion of autologous products that harbored abnormal cytogenetic clones led to an increased risk of poor graft function with the subsequent development of post-transplantation MDS and secondary leukemia [95].

Prior exposure to radiation therapy may also impair the hematopoietic microenvironment and negatively impact graft function. In a mouse model of BMT, irradiation caused profound and lasting changes in the expression of the endothelial trafficking molecules VCAM-1 and P-selectin, which were important for hematopoietic cell recruitment to the bone marrow niche [96]. The administration of clinically relevant doses of TBI-activated marrow p38 mitogen-activated protein kinase (MAPK) induced long-term bone marrow injury that resulted in a significant reduction in hematopoietic cell clonogenic function and increased HSC senescence [97]. These findings suggest that the health of the marrow microenvironment may be a limiting factor in supporting sustained engraftment of allogeneic and autologous hematopoietic cells. The clinical relevance of these observations with respect to GF is not established, but of interest.

Preparative regimen

The transplant preparative regimen can influence the GF rate. Attempts to overcome the relatively high GF rate in patients with SAA who received multiple pretransplantation transfusions included intensifying the conditioning regimen by combining CY 200…mg/kg with TBI or total lymphoid irradiation (TLI) [19,98]. Although GF rates were reduced with the combinations, overall survival was not improved owing to the higher rates of death from GVHD and interstitial pneumonia. Animal studies showed a synergistic immunosuppressive effect between CY and ATG for overcoming marrow allograft rejection, thereby obviating the need for TBI [99]. On the basis of these models, a regimen of CY and ATG was developed for patients with SAA and a reduced GF rate and improved overall survival was reported compared with historical data [100]. However, a prospective clinical trial in which patients were randomly assigned to receive CY alone or CY in combination with ATG reported a similar GF rate in both groups [101].

Two randomized studies failed to identify differences in the time to functional platelet and neutrophil engraftment or in GF rates when conventional full-dose fractionated TBI–CY was compared with BU–CY in chronic-phase CML patients who received unmanipulated marrow grafts [102,103]. Increasing the intensity of the transplant preparative regimen in already fully myeloablative conditioning did not decrease the risk of GF as the addition of Ara-C to a standard BU–CY transplantation regimen for pediatric patients did not impact the risk of GF or the time to platelet and neutrophil engraftment in recipients of autologous or allogeneic HCT [104].

In contrast to the observations following full-dose conditioning, increasing the intensity of host conditioning following some reduced-intensity regimens reduced the incidence of GF. Non-fatal GF occurred in 20% of 44 leukemia patients who received sublethal TBI with post-transplantation mycophenolate mofetil (MMF) and cyclosporine (CSP), and autologous hematopoietic cell recovery occurred in each case [105]. In a similar patient population, the addition of fludarabine to sublethal TBI reduced the GF rate to 12% [75]. The addition of sublethal TBI to other conditioning regimens did not reduce the GF rate. In a study of a 100 patients with acquired SAA, fludarabine, CY and ATG, administered with or without 2… Gy TBI, resulted in an equivalent GF rate of 17% [106].

Transplantation following RIC is associated with multi-lineage mixed chimerism that may persist for several months [107–109]. It is difficult to assess the impact of mixed chimerism on the risk of GF because often interventions such as immunosuppressive (IS) drug withdrawal, $CD34^+$ selected donor boosts, or donor lymphocyte infusions (DLIs) were employed [24,107–110]. These interventions were to promote conversion to full donor type yet they were not without risk and resulted in the development of GVHD in some patients. A transplant regimen of CY, ATG, and thymic irradiation with postgrafting IS consisting of CSP revealed that almost 30% of the patients developed GF by day +100 if the donor T-cell chimerism level on day +30 post-transplant was <50% [108]. The GF risk following conditioning with 2…Gy TBI ± fludarabine with post-transplantation IS consisting of MMF and CSP was 50% among patients who had donor T-cell levels below 25% by day +30 post-transplantation compared with a 4% GF rate if the donor T-cell level was 51–75% by this time [111]. In other studies, the post-transplant levels of donor T- and NK-cell chimerism at days +14 and +28 were also important predictors of GF [107,112].

Controlled experimental and clinical studies are required to understand better how an alteration in a preparative regimen impacts the kinetics of conversion to donor cell type and the incidence of GF.

Post-transplantation immune suppression

The importance of suppressing HVG reactions by using post-transplantation IS medication to prevent GF has been well demonstrated in preclinical models. In a preclinical dog model of BMT using dog leukocyte antigen (DLA)-identical littermates and sublethal TBI conditioning, CSP alone was insufficient to suppress HVG reactions and all recipients had non-fatal GF [113]. By comparison, post-transplantation immune suppression with methotrexate (MTX) and CSP led to prolonged hematopoietic chimerism in all cases, yet still just over half of the animals ultimately lost their grafts. The combination of MMF and CSP or of MMF and sirolimus led to stable chimeras in all recipients for at least 4 months [113,114]. In another canine transplantation model, extending the length of post-transplantation IS medication from 35 to 100 days facilitated stable donor engraftment [115]. These preclinical studies were instrumental in designing optimal combinations of post-transplantation IS medication to help prevent GF in clinical HCT using RIC.

The use of post-transplantation CY following RIC HLA haploidentical BMT was evaluated in 210 adult and pediatric patients with leukemia, MDS, and lymphoma [116]. The median time to adequate neutrophil recovery was 15 days and the GF rate was 13%. Almost all patients with GF in this study had autologous reconstitution. Although randomized studies do not exist, it seems that post-transplantation CY appears to mitigate the negative impact of haploidentical donors on the GF rate.

Graft source

Graft source for autologous and allogeneic HCT is covered in detail in Chapter 40. Briefly, in autologous HCT, the time to neutrophil and platelet recovery is more rapid with mobilized hematopoietic progenitor cells compared with BM, and there is no apparent difference in the GF rate [117]. The same observation is true following full-dose conditioning and HLA-matched, related allogeneic HCT; G-mobilized blood mononuclear cells impart a faster time to neutrophil and platelet engraftment compared with unstimulated BM, with no difference in the GF rate [118]. In contrast, in recipients of unrelated donor transplants, G-mobilized blood was associated with a lower GF rate (3%) than unstimulated BM (9%), and GF was the cause of death in 8% of BM recipients compared with 0% in the G-mobilized group ($p = 0.002$) [119]. In recipients of unrelated donor grafts, it may be preferable to consider a G-mobilized product in patients at higher risk for GF, such as those with uncontrolled or poorly controlled disease, or those with malignant diseases who have not received cytotoxic chemotherapy prior to transplant.

The biologic features of cord blood suggest that they are highly proliferative, which may be important in overcoming the limited number of cells that are obtained for transplantation. One issue that has consistently emerged irrespective of the degree of HLA match is the delayed time to blood count recovery following UCB transplantation. A CIBMTR report of pediatric acute leukemia patients who underwent transplantation between 1995 and 2003 compared the time to platelet and neutrophil count recovery in recipients of one- or two-allele mismatched unrelated donor BM compared with one- or two-allele mismatched single-unit UCB recipients and showed a significantly delayed time to count recovery in UCB recipients [120]. A similar report from the CIBMTR, the European Group for Blood and Marrow Transplantation (EBMT), and the National Cord Blood Program of the New York Blood Center also confirmed significantly delayed neutrophil and platelet recovery times among adult UCB transplant recipients [121]. To help overcome the delay in blood count recovery, practice standards have evolved, and since about 2010 the lower acceptable nucleated cell dose limit to use a single UCB unit has been 2.5×10^7 cells/kg bodyweight.

Although the use of a double UCB transplantation assured a higher cell dose, hematopoietic recovery still remained significantly delayed compared with recipients of matched and mismatched donor BM [122]. This study emphasized that the most significant barrier to more successful UCB transplants was the delayed neutrophil engraftment time, because a delayed neutrophil recovery time led to a significantly increased NRM from infection deaths. Strategies to reduce the period of neutropenia following UCB transplantation are being explored and include ex vivo expansion culture to augment the number of HSCs and progenitors in the UCB graft, coinfusion of TCD haploidentical PBPCs to bridge the period of neutropenia, and the injection of UCB cells directly into the patient's BM to reduce non-specific losses of HSCs and improve homing and engraftment [123].

Effect of cell numbers

Most studies demonstrated that, at least to some extent, a minimum threshold number of progenitor cells was required to ensure reliable neutrophil and platelet engraftment and reduce the risk of GF following autologous and allogeneic HCT.

Historically, the nucleated cell (NC) or mononuclear cell (MNC) dose was the surrogate to assess the HSC content in BM graft. In autologous HCT, the predictive value of NC or MNC dose with respect to the rapidity of hematopoietic recovery demonstrated no statistically significant correlation between the infused numbers of NCs/kg or MNCs/kg and the time to neutrophil or platelet recovery [124]. For allogeneic HCT, it was reported that 5×10^8 NCs/kg recipient weight was a reasonable estimate of the number of BM cells required for a successful transplant, whereas a dose of $<3 \times 10^8$ NCs/kg recipient weight correlated with an increased risk of GF following full-dose conditioning [125]. Subsequent studies regarding the predictive value of BM NC dose and the risk of GF following allogeneic HCT failed to yield consistent results.

In contrast to the NC dose, an increased number of granulocyte–macrophage colony-forming units (CFU-GMs) in the autograft positively correlated with more rapid time to neutrophil and platelet recovery. A threshold dose below $0.1–3 \times 10^4$ CFU-GMs/kg resulted in significant engraftment delays [126]. The CFU-GM assay, however, has limitations: there is imprecision in CFU-GM quantification, especially when the progenitor content is low, there is a subjective nature to the data interpretation, with high interlaboratory variability, there is a requirement for expensive biologic reagents, and there is an approximately 2-week delay before results are obtained. In some transplant populations there may be value in using this assay to assess the potency of the graft. A study of the kinetics of engraftment in 435 primarily pediatric patients receiving a single-unit unrelated UCB transplant after conventional full-dose conditioning demonstrated that pre-cryopreserved higher colony-forming unit (CFU) dosing was the only graft characteristic strongly predictive of neutrophil and platelet engraftment [127]. In comparison, the $CD34^+$ cell dose and TNC/kg were only weakly predictive.

The expression of cell surface CD34 can be rapidly assessed within a few hours by flow cytometry. In autologous HCT, the infusion of $>2 \times 10^6$ $CD34^+$ cells/kg recipient weight was suggested as the minimum target dose for acceptable engraftment kinetics [128]. A more rapid neutrophil and platelet reconstitution was consistently observed by the infusion of higher $CD34^+$ cell doses [129]. Platelet recovery appeared most affected by grafts with low $CD34^+$ cell numbers. Patients considered "poor mobilizers," defined as a collection of $<1 \times 10^6$ $CD34^+$ cells/kg, safely underwent autologous HCT with no difference in overall survival, albeit 50% of the patients failed to reach a platelet count of $>10^5/\mu L$ by day +100 after transplant [130]. An absolute minimum $CD34^+$ cell dose below which autologous HCT is not recommended has not been defined. It is the opinion of the authors that BM harvesting to supplement a graft with a $CD34^+$ cell dose below 1×10^6 be considered.

There are inconsistent results regarding the impact of the $CD34^+$ cell dose and its relationship to GF following full-dose allogeneic HCT. This may reflect that a minimum threshold number of cells is required to promote engraftment above which there is no correlation. The widespread practice of infusing as many cells as possible to give the recipient the best possible chance for a rapid and complete hematologic recovery has made it difficult to analyze the effect of cell dose on the risk of GF. Furthermore, comparisons among studies is difficult because patients differ with respect to the preparative regimen, underlying disease, disease status, pre-transplantation therapy received, post-transplant IS medications, donor–recipient gender mismatch, degree of HLA compatibility, and a variety of other patient- and donor-specific factors. Overall, it appears that within the general range of cells collected in an unmanipulated graft, its composition does not appear to impact the risk of GF and the time to platelet and neutrophil recovery following full-dose conditioning with matched related and unrelated donors [131]. In mismatched and haploidentical HCT, $CD34^+$ cell doses impacted the time to engraftment [132]. When $CD34^+$ cell doses were $<8 \times 10^6$ cells/kg recipient weight, the time to blood count recovery was significantly delayed. Many centers target a $CD34^+$ cell dose of over 10×10^6 cells/kg recipient weight when considering mismatched and haploidentical HCT.

Several studies confirmed that following RIC, high doses of donor $CD34^+$ cells led to more rapid T-cell engraftment with a lower risk of GF [133]. It was also reported that a higher $CD8^+$ T-cell dose in the donor inoculum correlated with a lower risk of GF following RIC [134].

It is likely that as our understanding of $CD34^+$ and effector cell populations improves, protocols that manipulate graft content to reduce GF will be developed for autologous and allogeneic HCT.

Graft manipulation

Graft manipulation by any of a number of means may pose a potential increased risk for GF. However, the $CD34^+$ cell selection of BM and blood-derived autografts in patients with NHL and breast cancer did not adversely affect the time to neutrophil and platelet recovery or the GF rate [135,136]. In contrast, unmanipulated grafts were more effective in mediating stable engraftment following allogeneic HCT compared with grafts selectively enriched or depleted for one of a variety of cell populations, and this is true irrespective of the intensity of transplant conditioning regimen. Pan-TCD or selective $CD8^+$ and $CD6^+$ TCD of the donor inoculum reduced the risk of acute GVHD, but survival in these studies was not improved because of the increased risk of death from GF, tumor relapse, and infection [28,29].

Strategies for risk reduction of graft failure

Prior to pursuing HCT, pre- and post-transplantation strategies that address and mitigate the patient's risk factors for GF (Table 77.2) should be considered. For example, it seems reasonable to screen recipients of mismatched or unrelated donor grafts for DSAs, and if positive, treatments to decrease DSAs and reduce the GF risk should be considered [137]. Given the improved outcomes with unrelated donor HCT and the concern about advanced donor age on outcomes, including an increased risk of GF, it may be advantageous to consider a young unrelated donor, or even UCB, over an old related donor, albeit the cut-off ages for this are not defined

[138]. It may be helpful to treat patients with massive splenomegaly prior to transplant to reduce the potential negative impact that this may have on donor cell engraftment. In autologous HCT, appropriate cell numbers should be adjusted whenever possible to meet required needs, and occasionally a BM harvest to supplement a low CD34$^+$ cell yield from a patient who is a "poor mobilizer" may be required. In allogeneic HCT, a higher cell inoculum appears to enhance the probability of sustained engraftment in patients transplanted for non-malignant hematopoietic disorders such as SAA, and also in recipients of grafts from HLA-mismatched donors [139]. The higher CD34$^+$ cell dose has to be balanced against a potential increased risk of chronic GVHD [140].

Monitoring of graft performance

The evaluation of graft function may be performed at different levels, including the assessment of adequate production of blood cells, assessment of hematopoietic precursors in the marrow, and evaluation of stromal cell function. Chimerism studies of T, B, NK, and myeloid cells have become an important part of graft monitoring, particularly for patients transplanted after RIC, or recipients of mismatched grafts, or those transplanted for non-malignant diseases. Studies that evaluate the kinetic change of the proportion of donor cells are key to project the fate of the graft, determine the risk of GF, and possibly to direct interventions.

Interventions for graft failure

Strategies for the treatment for early and late GF following autologous and allogeneic HCT are highlighted in Table 77.3.

Use of autologous back-up

In circumstances where the autologous product has been manipulated, for example by CD34$^+$ cell enrichment, it is prudent to store an unmanipulated portion of the graft, as infusion of the back-up has restored hematopoiesis following GF [23]. The practice at one of the authors' institutions (R.L., Stanford University Medical Center) is to collect enough cells to ensure that all autologous products, whether manipulated or not, are split to secure a back-up cell dose of $>2 \times 10^6$ CD34$^+$ cells/kg recipient weight. If following GF autologous back-up cells are not available, a search for an allogeneic donor graft should be initiated. In this instance, an RIC regimen should be considered given the relatively close proximity to the autologous transplant. On another note, autologous rescue has been successful in restoring hematopoiesis in patients with GF after allogeneic HCT [23,24]. The relatively low risk of GF following allogeneic HCT and the inherent difficulty in collecting uncontaminated autologous cells in patients with hematologic neoplasms, or with marrow failure syndromes, make the routine decision to store autologous products in allogeneic transplant recipients problematic.

Table 77.3 Treatment strategies for graft failure

Graft failure following	Treatment
Autologous HCT	Autologous back-up should be available, especially if product is to be manipulated Hematopoietic growth factor support Early consideration for allogeneic HCT
Allogeneic HCT	Autologous back-up should be considered, especially if an alternative donor is used (cord blood or mismatched donor) Trial of hematopoietic growth factor support Alterations in immune suppression medication may help prevent graft rejection DLI or additional cell infusions to convert persistent mixed or falling chimerism to full donor type CD34$^+$ cell boost for poor graft function Regrafting using same or alternative donor

Use of growth factors after graft dysfunction

Myeloid growth factors are reported to shorten significantly the time to neutrophil recovery following the infusion of an autologous graft [141]. The impact on the time to platelet recovery is less clear. Growth factors have been used for the treatment of GF following autologous HCT, with variable improvements in blood counts leading to adequate myelopoiesis and long-term disease-free survival reported in some patients [142]. In contrast, post-transplantation growth factor support for patients with GF who received a chemically purged autologous product consistently confirmed a lack of response [143]. There are no data comparing GM-CSF with G-CSF. A trial of post-transplantation growth factors is a reasonable approach for graft dysfunction following autologous HCT while consideration for a more definitive therapeutic intervention is being evaluated.

The role of growth factors in patients with poor graft function, or GF, following allogeneic HCT remains unclear. A randomized study in patients with GF after related or unrelated allogeneic HCT demonstrated that sequential GM-CSF and G-CSF improved the 100-day survival compared with GM-CSF alone [144]. It is reasonable to consider hematopoietic growth factor support as an adjunct in the management of low blood counts following allogeneic HCT, and depending on the cause this therapy may or may not be effective.

Changes in immune suppression

Preclinical models of BM transplantation demonstrated that following RIC, suboptimal immune suppression medication immediately post-transplantation increased the risk of early GF [113], whereas adequate dosing supported engraftment by inhibiting HVG reactions [114,115]. In instances of persistent mixed or declining donor-cell chimerism, it remains unclear whether immune suppression drug withdrawal will hasten or prevent graft loss. A number of studies suggested a modest improvement in preventing GF, and subsequent disease relapse, following preemptive fast (<7 days) immune suppression medication withdrawal aimed at converting patients with declining or persistent mixed chimerism to full donor type [145,146]. Controlled studies are required to define how an alteration in post-transplantation immune suppression will affect engraftment, relapse, and GF.

Use of donor lymphocyte infusion

Unstimulated DLI was administered preemptively (preemptive donor lymphocyte infusion, pDLI) to SAA patients considered at high risk for GF because of decreasing levels of donor-cell chimerism [147]. In that study, low-dose pDLI promoted the conversion to complete donor type and no patient experienced GF.

Following RIC, persistent mixed chimerism, or declining levels of donor cells, either CD3$^+$ or leukemia lineage (i.e. B, T, or myeloid lineage) was associated with an increased risk for GF and leukemia relapse in adult and pediatric transplant recipients [146,148–152]. The administration of pDLI after day 100 to patients who, despite being withdrawn from immune suppression medication, persisted with low (<50%) or declining levels of donor CD3$^+$ cells, resulted in approximately 50% of recipients

Table 77.4 Second transplants for graft failure

Study	*n*	Graft failure	Diagnosis	Donor for 2nd transplant	Source of cells	Same donor	Median time to 2nd transplant (days)	Regimen before 2nd transplant	Response (%)	Outcome

1°GF, primary graft failure; 2°GF, secondary graft failure; ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; BM, bone marrow; CML, chronic myelogenous leukemia; CN, chronic myeloid neoplasms; FA, Fanconi's anemia; Flud, fludarabine; MDS, myelodysplastic syndrome; MRD, matched related donor; NHL, non-Hodgkin lymphoma; PB, peripheral blood; OS, overall survival; RCC, renal cell cancer; SAA, severe aplastic anemia; TCD, T-cell-depleted; Thal, thalassemia; TBI, total body irradiation; UCB, umbilical cord blood.

converting to complete donor type. The majority of the patients required multiple pDLI before converting [110,153]. Although the data are provocative, it remains uncertain how many would have become full donor chimeras without an intervention. The pDLI was associated with the development of acute GVHD in a significant proportion of recipients [108,110,153]. Selective depletion of cellular subsets within the DLI might promote conversion to full donor type, yet not precipitate GVHD. In this respect, the removal of naïve and a subset of memory T cells may be a possible candidate [33]. The timing of when to administer pDLI for GF prevention is unclear and requires careful consideration of competing risks and benefits. Is conversion from mixed chimerism to complete donor type absolutely necessary? Conversion to full donor chimerism was not required for graft versus tumor (GVT) reactions in some studies, whereas others have suggested that sustained GVT activity requires conversion to full donor chimerism [107,108,146,148–152].

Use of $CD34^+$ boost

Poor graft function after allogeneic HCT is defined by at least two lines of cytopenia beyond 28 days after transplantation in patients with complete or nearly complete donor chimerism [21]. In patients with poor graft function, a $CD34^+$ selected cell boost following G-CSF mobilization was associated with a high likelihood of hematopoietic cell recovery and a low risk of GVHD [21]. Patients did not receive conditioning prior to the $CD34^+$ cell boost. It is unclear how long one should wait before requesting a boost of cells. Once the diagnosis of poor graft function is established, we consider a few weeks of severe cytopenia to be a reasonable period, keeping in mind that it may take another several weeks actually to collect the cells. Poor graft function may result from a viral infection, a medication side effect, and GVHD, and identifying the underlying cause should be the primary focus as appropriate treatment may establish that the cytopenias are transitory.

Table 77.5 Considerations for a second allogeneic HCT for graft failure

- Should the same or a different donor be used? Likely does not matter, check for DSA
- Should BM or G-mobilized blood be used? If HLA matched may not matter, second transplants have increased risk of acute GVHD
- When to use a $CD34^+$ selected boost? Predominantly for poor graft function
- When to use an unmanipulated graft? Predominantly for graft rejection
- Should a preparative regimen be used? Yes, preference for RIC
- Is post-second transplantation IS medication necessary? Yes
- What is the role of DLI for converting mixed chimerism? Evidence supports DLI to convert mixed to full donor type, yet no evidence to support that DLI prevents falling chimerism that would otherwise lead to graft loss

Regrafting

Regrafting with a second allogeneic HCT from the same donor, or an alternative, can successfully rescue patients with GF (Table 77.4) [154–159]. The largest of the studies was a retrospective multicenter report that reviewed 82 consecutive second allogeneic transplants for primary (n = 28) and secondary (n = 54) GF in patients with acute and chronic leukemia and SAA who received full-dose conditioning for the first transplant [154]. The same donor was used for both transplants in 56 cases. All patients received RIC prior to the second transplant. The probability of neutrophil recovery was 75% and platelet recovery to $>50 \times 10^9$/L, was 30%. The estimated 3-year overall survival was 30%, which was superior to the 8% reported for GF in SAA patients without a second transplant [125]. A more recent report of second allogeneic transplants for GF in 38 consecutive patients, predominantly with hematologic malignancies, used a uniform salvage transplant regimen of fludarabine and either 3 or 4…Gy TBI [159]. Sustained engraftment was achieved in 33 patients and the estimated 4-year survival was 42%.

Some considerations regarding salvage second transplants for GF are shown in Table 77.5. There is a requirement for transplant conditioning, of which RIC is recommended. Whether the second transplant used a graft from the original or a different donor did not appear to impact the likelihood for successful engraftment; however, there appeared to be a relatively high incidence of acute GVHD, and disease recurrence after resolution of graft failure remained an important cause of treatment failure.

Conclusion

Successful HCT is achieved when the infused hematopoietic progenitor cells traffic to their BM niche and restore hematopoiesis. Graft failure refers to an inadequate recovery of blood cells following HCT and remains a relatively uncommon complication, yet its presence can be associated with significant morbidity and mortality. Graft failure is the end-stage result of many contributing factors. A detailed evaluation of the underlying cause of graft dysfunction is important because appropriate treatment may establish that the cytopenias are transitory. Although more study is needed, several treatment options are available to overcome GF and improve the long-term survival in transplant recipients.

CHAPTER 78

Blood Group Incompatibilities and Hemolytic Complications of Hematopoietic Cell Transplantation

Margaret R. O'Donnell
City of Hope Medical Center, Duarte, CA, USA

Introduction

The etiologies of hemolytic disorders following hematopoietic cell transplantation (HCT) can be categorized as either immune mediated or complications related to thrombotic microangiopathy (TMA) syndromes. The majority of immune-mediated hemolytic reactions are caused by alloantibodies directed at red blood cell (RBC) antigens in blood group-incompatible donor–recipient pairs. Immune-mediated hemolysis is less common but can be seen following both allogeneic and autologous HCT. In these instances, hemolysis may be related to drugs, infections or recurrent disease (primarily in lymphoproliferative disorders) or be a manifestation of chronic graft-versus-host disease (GVHD). The factors leading to hemolysis in the context of thrombotic microangiopathy following HCT are poorly understood. The supposition has been that endothelial cells injury caused by radiation, dose-intensive chemotherapy, immunosuppressive agents such as tacrolimus (FK506), sirolimus, or cyclosporine (CSP), or cytokine release associated with GVHD are responsible for thrombus formation in small vessel beds. This chapter addresses the issues of prevention, diagnosis, and treatment of these disorders in the context of HCT.

Hemolytic complications of ABO incompatibility

The inheritance of blood group antigens (ABO, Rh, Jk, etc.) is independent of that of the human leukocyte antigen (HLA) complex present on tissues. In most series of sibling allogeneic HCT, there is discordance of ABO groups in 30–40% of donor–recipient pairs with similar or slightly higher rates in unrelated donor (URD) HCT. Although ABO incompatibility may increase the complexity of HCT, it is not usually viewed as a barrier to successful engraftment of myeloid or megakaryocytic precursors and has not been shown to affect the incidence of GVHD. Recipients of ABO-incompatible HCT products do require more RBC and platelet transfusions than those receiving compatible products with a subset of patients with major ABO mismatches developing pure red cell aplasia (PRCA), which usually resolves within a few weeks to months.

ABO incompatibility is defined as major when the recipient plasma contains isohemagglutinins (HAs) against donor RBC antigens; it is a minor mismatch if the donor has HAs directed against recipient RBC antigens and bidirectional if both features are present. There are two scenarios for the development of hemolysis in the first weeks post HCT [1–5] (Table 78.1):

1. Pre-existing HAs cause immediate and ongoing lysis of RBCs as long as the HAs persist (major or bidirectional).
2. Generation of new HAs by passenger lymphocytes in the graft as a response to foreign antigens in the recipient causes delayed hemolysis usually 2–4 weeks following HCT (minor and bidirectional).

The time of onset and duration of hemolysis are affected by the titer of HAs and the rate of clearance and also the quantity of target antigen available. In a proportion of major ABO-incompatible HCT, the HAs target not just circulating RBCs but also early marrow precursors expressing the antigen at the level of the colony-forming unit – erythroid (CFU-E), leading to PRCA [6–9]. Other factors that may have implications for the development of hemolysis are the conditioning regimen [high-dose versus reduced-intensity conditioning (RIC) versus non-myeloablative (NMA)], HCT source [marrow versus peripheral blood (PB/HCT)], and donor [sibling versus URD versus umbilical cord blood (UCB)] and immunosuppressive agents. The development of RIC regimens to accommodate a wider range of patients creates an environment in which donor and host hematopoiesis coexist for protracted periods; this has led to concerns about the possibility of higher rates of chronic hemolysis and PRCA [10–12]. Peripheral blood HCT products carry a 10-fold higher number of T-lymphocytes, which are less activated than T cells in marrow products. B-cell recovery also is reported to occur earlier post-PB/HCT with augmented immunoglobulin production early post-HCT compared with marrow, which might lead to a higher probability of delayed hemolysis in minor incompatible HCTs.

Delayed RBC production and increased transfusion requirements have been documented with ABO incompatibility in several studies in both high-dose and RIC settings. Worel et al. showed that the generation of reticulocyte counts >3% took a median of 32 days for major ABO mismatches versus 21 and 22 days for matched and minor mismatched recipients, respectively, and the number of RBC transfusions up to day 100 following ablative marrow HCT doubled (12 for major versus six for match and eight for minor) ($p = 0.045$) [13]. In 2001, Bolan et al. reported that RBC production was delayed beyond 100 days in over 60% of patients treated with RIC [14]. Early post-HCT, RBC production may appear adequate in RIC and NMA recipients due to autologous RBC recovery; however, as the chimeric balance progressively becomes donor in origin, autologous RBC production declines during the second to fourth months post-RIC HCT. The agents used in RIC (fludarabine, cyclophosphamide,

Table 78.1 Immunohematologic problems of ABO-incompatible hematopoietic cell transplantation (HCT)

Major mismatch (20%)
Example: Recipient O, Donor A, B, AB *or* Recipient A or B, Donor AB
  Immediate hemolysis of RBC infused with graft
  Delayed hemolysis of donor RBCs by persistent recipient HAs
  Delayed erythrocyte production
  Pure red cell aplasia

Minor mismatch (22–24%)
Example: Recipient A, B, or AB, Donor O *or* Recipient AB, Donor A or B
  Immediate hemolysis of recipient RBCs by donor-derived HAs in graft
  Delayed hemolysis of recipient RBCs by newly generated HAs from donor lymphocytes ("passage lymphocyte")

Bidirectional mismatch (1–2%)
Example: Donor A, Recipient B *or* vice versa
  Both immediate and delayed hemolysis are possible with HAs of donor against recipient RBCs and recipient HAs directed against donor RBCs

melphalan, and low dose radiation) allow the persistence of recipient B cells and plasma cells for much longer periods than in ablative conditioning [15]. During the period of mixed chimerism, these cells are capable of continuing production of recipient-type HA. Although marrow cultures confirm that engraftment of erythroid precursors at the level of burst-forming units – erythroid (BFU-E) occurs in the same ratio as myeloid and megakaryocytic precursors, later erythroid precursors that express ABH antigens starting at the level of CFU-E often do not appear on marrow biopsy until immunoglobulin G (IgG) and IgM titers of recipient HA fall to 1:1 [16]. The reported incidence of PRCA following RIC has varied widely from 6 to 50%, compared with rates of 5–16% post-high-dose conditioning [14]. Griffith et al. followed chimerism studies including plasma cells and B cells post-fludarabine/cyclophosphamide conditioning in 12 ABO-mismatched recipients with renal cell carcinoma or other malignancy. Six developed PRCA that persisted for 3–4 months after T-cell and myeloid hematopoiesis had shifted to 100% donor; in all six patients with PRCA, recipient plasma cells were detectable by chimerism studies (5–42%) and persisted longer than B cells, implying that the plasma cells were the source of the HA production [17]. In a recent report from the M.D. Anderson Cancer Center at Houston, TX, covering 162 patients who received major ABO-incompatible stem cells following RIC with a busulfan-based regimen, the incidence of PRCA was 7.5%. The median time to appearance of donor RBCs was 30 days for the majority of patients without PRCA versus 218 days for the PRCA recipients who remained transfusion dependent beyond 500 days [18]. Wang et al. summarized the Seattle experience for 503 patients who received NMA conditioning regimens of a single fraction of total body irradiation (TBI) 2…Gy alone or combined with fludarabine. Transfusion requirements for both PRBCs and platelets were less for NMA recipients with 25% of patients not requiring PRBCs for NMA versus 4% for ablative regimens. As expected, rates of PRBC requirements were higher in ABO-incompatible or bidirectional pairs than in ABO-matched or minor mismatched pairs whereas there was no difference in platelet transfusion requirements. The median time to disappearance of HA was 48 days for IgG and 47 days for IgM among 102 major or bidirectionally mismatched pairs; nine recipients still had detectable titers at the time of last follow-up. Time to clearance was related to pre-transplant titers. There was no significant difference in graft failure, GVHD, or survival based on blood group mismatch. The report did not comment on the incidence of PRCA [19].

There have also been reports that GVHD regimens of CSP alone or combined with prednisone create a mileau conducive to persistence of HA production since CSP (and by inference FK506) permits B cells to remain longer than combinations that include methotrexate or mycophenolate mofetil (MMF) along with CSP [20]. The impact of sirolimus combined with FK506 on the clearance of HA is uncertain. The development of acute GVHD appears to accelerate the clearance of HA, possibly due to a graft-versus-plasma cell effect [21]. In the M.D. Anderson series which used FK506 and methotrexate, the incidence of GVHD in the non-PRCA patients was 27% but none of the PRCA patients had GVHD prior to recovery of RBC engraftment.

Delayed hemolytic reactions

In minor ABO-mismatched HCT, hemolysis, which may be severe and occasionally fatal, can occur either immediately due to existing IgM or IgG HA in the product or emerge abruptly 5–17 days post-transplant as a result of the development of new HA generated by "passenger" B-lymphocytes transferred from the donor at the time of transplantation [5,22,23]. Significant hemolysis occurs in 10–15% of minor mismatched adult HCT grafts compared with 10% for renal allografts and 70% for heart–lung recipients. The incidence of "passenger lymphocyte syndrome" increases with the B-cell content of the graft; it is therefore reasonable to expect a higher incidence of hemolysis with peripheral blood progenitor cell (PBPC) products that contain a 10-fold increase in $CD10^+$ and $CD20^+$ cells compared with marrow grafts [23,24]. The use of granulocyte colony-stimulating factor (G-CSF) to mobilize donor PBPCs can also modulate T-lymphocyte cytokine production in such a way that promotes antibody production. Although ABO antigens are the most common targets, hemolysis has also been reported against Rh, Jka, Kidd, and Lewis blood group antigens [25–28]. Several factors influence the severity of the hemolysis, including rapidity of rise of donor antibody in the recipient post-transplant, secretor status, and rapidity of engraftment (i.e. type of graft) [23,24,29]. Massive hemolysis in which most, if not all, recipient RBCs are lysed over 2–3 days seems to be complement mediated, analogous to post-transfusion purpura. The incidence of hemolysis following minor mismatched HCT has varied from 5–10% for marrow up to 33% for PB/HCT. One study evaluated the rate of HA production following 24 PBPC and 14 UCB minor mismatched products. Fifteen of 24 PBPC recipients were found to have donor-derived HAs between 6 and 88 days post-HCT; 50% of those with detectable HAs showed some evidence of hemolysis. None of the UCB recipients developed HAs, which correlates with the data that the naïve B cells present in the UCB graft lack the exposure to ABH antigens necessary to generate HAs [29].

Management of ABO and Rh incompatibility

The strategies for managing blood product support is outlined in Table 78.2. As a general rule, Group O RBCs are the preferred products in the immediate pre- and post-HCT period, thereby diluting the percentage of RBC targets for donor-generated HAs in minor or bidirectional mismatched HCT [30–33]. Group O RBCs are the RBC product of choice upon selection of an ABO-mismatched donor for an imminent HCT procedure. Prior to HCT conditioning, both recipient and donor HA titers should be ascertained. If the recipient has high titers against donor RBC antigen, the RBC content of the infused product will be minimized. Plasma exchange should be considered using 5% albumin or plasma lacking that antibody shortly before HCT in patients with titers ≥1:256.

Table 78.2 Management of blood support for ABO-incompatible transplant recipients

	RBCs	**Plasma**
Major mismatch		
Example: Recipient O Donor A	Remove RBCs from HCT product to <25…mL or <1…mL/kg Transfuse O cells pre- and post-transplant	Give donor-type platelets and plasma and volume-reduced platelet product if not available. If recipient anti-A titer is >1:256, consider: Plasma exchange pre-transplant
Minor mismatch		
Example: Recipient B Donor O	Transfuse group O cells. Red cell exchange with group O cells pre-HCT, or hyper-transfuse with group O cells	1. Remove plasma from HCT graft to prevent immediate hemolysis if donor titer ≥1:256 or antibody is hemolytic 2. Give platelet and plasma lacking anti-B isohemagglutinin or volume-reduced platelets 3. Monitor direct Coombs test beginning day +1 then every 2–3 days ending day +21 to monitor for hemolysis caused by "passenger" lymphocyte syndrome
Bidirectional mismatch		
Example: Recipient B Donor A	Transfuse O cells Remove RBCs from HCT product Red cell exchange with group O cells, or hyper-transfuse with group O cells	1. Remove plasma from HCT(M) to prevent immediate hemolysis if donor titer >1:256 or antibody is hemolytic 2. Use group AB plasma and platelet products before and after transplant, or volume-reduced platelets 3. Consider plasma exchange for isohemagglutinin titer >1:256 4. Monitor direct Coombs test beginning day +1 then every 2–3 days ending day +21 to monitor for hemolysis caused by "passenger" lymphocyte syndrome
Rh incompatible Major Minor	Transfuse with group O negative cells pre- and post-transplant. Possible RBC-depleting HPC(M) from an Rh-positive product if recipient has a high titer anti-Rh antibody	Consider Rhogam

A typical one plasma volume exchange will remove approximately 60–70% of circulating antibodies, and since drug levels will be affected by the exchange, redosing certain regimen drugs might need to be considered. RBC exchange prior to HCT has been used to minimize the late hemolytic reactions seen 5–16 days post-infusion in minor ABO-mismatched recipients with high titers against recipient RBCs; these procedures are usually performed between 2 weeks and up to day −3 before HCT infusion after immunosuppression has been started to prevent rebound phenomena. A one RBC volume exchange with group O RBCs will provide the patient with approximately 60% of group O RBCs at the end of the procedure. The pre-transplant titers are not always predictive of the severity of delayed hemolysis in the "passenger lymphocyte" syndrome, hence exchange transfusions are being used less frequently. Some suggest that RBC and platelet products should be volume reduced post-HCT to minimize infusion of HAs in the plasma [33], whereas others propose infusing donor-type fresh frozen plasma (FFP) to provide a non-cellular source of A or B antigen to absorb recipient HAs [34].

Some authors have also reported using small aliquots of donor RBC 12–24 hours before HCT. This intervention requires forced alkaline diuresis and intensive monitoring for hemolytic reaction [35]. Hyper-transfusion with group O RBCs prior to day 0 has also been utilized by some centers. One example of hyper-transfusion is to give one unit of group O RBC to an adult patient every day for 3–4 days while the patient is receiving the conditioning regimen. An important aspect in managing immediate and delayed hemolysis for ABO-mismatched transplantation is product preparation. Peripheral blood hematopoietic stem-cell product (HPC-A) usually contains less than 20…mL of RBCs, but RBC depletion is often performed on a major ABO-incompatible marrow product by using either dextran sedimentation or centrifugation on an automated apheresis machine. Reduction of HAs by reducing the plasma volume of a minor ABO-incompatible marrow or apheresis stem-cell product is also commonly performed when the donor HA titer is greater than 1:256 or if the antibody is hemolytic. Although these measures are fairly effective in preventing immediate hemolysis in major mismatches;, 10% of patients receiving myeloablative and up 35% of patients receiving RIC HCT will develop delayed hemolysis.

Following HCT, patients with ABO incompatibility should be monitored clinically, as well as by the blood bank. Typically, an anti-A and/or anti-B titer will be performed 2 weeks to 1 month post-transplant on a major or a major/minor ABO-incompatible transplants. A direct Coombs test will be performed on day +1 and then every 2 days, ending on day +21 for minor and major/minor ABO-incompatible transplants. Clinical monitoring for evidence of hemolysis includes lactic dehydrogenase (LDH), reticulocyte counts, and bilirubin two or three times per week in the first 21 days post-HCT when the risk for acute hemolysis is highest. Patients with major mismatches and high HA titers pre-HCT are particularly at risk for delay of RBC engraftment and PRCA. HA titers in recipients with major mismatches should be monitored at least twice monthly when clinically indicated. Patients with rising titers and increasing transfusion requirements merit marrow evaluation to exclude PRCA. Clearance of HAs appears to be affected by both donor source and GVHD. Investigators in Seattle examined the rate of fall of HA titers in 383 major or bidirectional ABO-mismatched HCT recipients following ablative conditioning [36]. The time to undetectable titers was significantly shorter (46 versus 61 days, p = 0.016) in unrelated compared with sibling recipients. Among related donor–recipient pairs, those who developed GVHD had a twofold more rapid decline in antibody titers. In this study, ABO incompatibility did not affect the incidence of GVHD or survival. Remberger et al. reported that major ABO mismatch was a significant risk factor for graft failure among 224 URD HCT recipients who received fully ablative conditioning and T-cell depletion as a component of GVHD prophylaxis. The rate of primary and secondary graft failure was 7.5% for ABO major mismatch and 0.6% for matched donor–recipient pairs [37]. Graft failure has not been reported with high frequency in non-T-depleted studies. In two other studies, ABO incompatibility did affect survival at day 100 in subgroups of patients (chronic myelogenous leukemia patients in one and acute myeloid leukemia and myelodysplasia in the other) [14,38]. Neither report specified the factors influencing the poorer outcomes for ABO-incompatible HCT. One may speculate that more protracted transfusional support requiring indwelling venous access devices, which placed patients at higher risk of infection, might be a factor. Iron overload is a potential deleterious condition for those patients who developed PRCA.

Two large studies of the impact of ABO incompatibility of HCT outcome were compiled by the Center for International Blood and Marrow Transplant Research (CIBMTR) and the National Marrow Donor Program (NMDP). The CIBMTR study evaluated 3103 sibling ablative HCTs performed between 1990 and 1998 with CSP/methotrexate for GVHD prophylaxis for early-stage leukemia. Two-thirds of the recipients were ABO matched and 14% were major, 14% minor and 4% bidirectional mismatches. There were no differences in survival, relapse, transplant-related mortality, or acute and chronic GVHD. The only differences were a higher incidence of grade II–IV GVHD in bidirectional mismatched pairs and a longer RBC transfusion dependence for major mismatches [39]. In the NMDP report on almost 7000 donor–recipient pairs of which fewer than 40% were ABO matched, there was no difference in mortality or survival based on ABO groupings [40].The registry data from Japan showed no difference in acute GVHD but did show a higher rate of non-relapse mortality with both major and minor mismatches and a lower overall survival for major incompatible transplants [41]. The French registry data for over 1000 reduced-intensity transplants from both sibling and URD pairs showed increased non-relapse mortality and decreased overall survival for minor mismatch recipients[42]. The reasons for these differences are unclear.

Despite immunosuppression, patients can also develop alloimmunization to non-ABO RBC antigens post-HCT, most commonly involving Rh, Kell, or Kidd (Jk) antigens. Development of non-ABO antibodies has been reported in high frequency in patients receiving ABO incompatible HCT: 9.6% versus 1.6% for those receiving ABO matched products [25]. De la Rubia et al. [26] reported a 3.7% incidence of detection of new alloimmunization to Jka, K, M, Le, and Rh antigens, usually within the first 30 days post-HCT. In the majority of cases in which the specificity of the antibody was identified by elutriation from RBCs, the antibody was directed at antigens that were not detected in either the donor or recipient at the time of HCT. The HAs could have been produced by either residual host- or donor-derived lymphocytes in response to new RBC antigens presented post-HCT. Clinically, the agglutinins that develop in response to antigens that are different from those expressed on either donor or recipient RBCs have little hemolysis associated with them compared with fairly severe hemolytic reactions that have been seen with Rh– donor lymphocytes infused into Rh+ recipients. However, there have been two reports of severe hemolysis associated with the Jka system. In both instances, the donor had previously been sensitized to Jka but the method used for the pre-transplantation antibody screen did not detect the Jka antibody. It is not uncommon for an individual with known anti-Jka to have no serologically identifiable serum antibody a few months after the antibody was originally identified, making the risk of a clinically significant hemolytic event higher in Jka+ recipients [26,28], but overall, hemolysis due to non-ABO RBC antibodies post-ABO-incompatible transplants is not common.

Treatment of pure red cell aplasia

PRCA represents the most extreme form of hemolytic reaction post-HCT with recipient HAs targeting medullary precursors at the CFU-E stage, which is the earliest point of ABH antigen presentation. Recent reports suggest that there is a difference in both incidence and timing of this complication dependent upon the conditioning regimen. In high-dose conditioning, the incidence is lower and appears as an early and prolonged transfusion dependence whereas RIC recipients often have early autologous RBC production when the donor graft is just emerging with a later development of RBC dependence. RBC production usually returns within 3–4 weeks following the disappearance of circulating HA; however, some patients have remained RBC dependent for over 5 years [43]. In the majority of cases, tapering of immunosuppression permits a "graft-versus-plasma or B-cell" effect that shuts off HA production by either memory B cells or plasma cells. Other strategies have employed pharmacologic doses of erythropoietin alone or combined with steroids [44–46]. In more refractory cases, plasma exchange or the use of rituximab has been successful; rarely, donor lymphocyte infusion has been used to promote full donor chimerism and to ablate HA production, albeit at the risk of inducing acute GVHD [47–50]. Poon and Koh recently reported their experience using 4-weekly doses of bortezomib to target the mature plasma cells that were sustaining HA production in a patient who had failed all of the above therapies. Within 1 month of starting therapy the HAs were undetectable, although it was a further 3 months before the patient became transfusion independent [51].

In addition to PRCA associated with ABO incompatibility, aplasia has also been reported in conjunction with parvovirus B19 and human herpes virus 6 (HHV6) infections in both HCT and solid organ transplantation [52,53]. Most of these patients responded to Ig administration and treatment of the infection. Two children with hepatic allografts were reported to develop PRCA associated with FK506, which resolved when the drug was withdrawn; four renal allograft recipients developed PRCA associated with MMF [54,55]. In situations where PRCA develops outside the setting of major ABO incompatibility, a change in calcineurin inhibitor from FK506 to CSP or discontinuation of MMF may produce red cell recovery.

Non-ABO-related Coombs-positive autoimmune hemolytic anemia (AIHA) can also develop late post-HCT as an autoimmune manifestation of chronic GVHD [56]. Drugs such as antibiotics and fludarabine or infections with mycoplasma may also produce hemolysis. Impaired B-cell regulation may occur as a consequence of functional or quantitative T-cell depletion of the HCT product, with an AIHA incidence of 3% in one large series.

Patients who develop AIHA after HCT usually receive the same battery of immunosuppressive agents as non-transplant patients: steroids, immunoglobulin, rituximab, or splenectomy and also less conventional approaches such as plasma immunoabsorption, vincristine, or reinfusion of aliquots of donor T cells to exert immunoregulation on the autoreactive T cells.

Hemolysis and thrombotic microangiopathy (TMA) syndrome

Thrombotic microangiopathy describes syndromes of Coombs-negative hemolysis associated with RBC fragmentation, often combined with clinical features of renal or neurologic dysfunction and thrombocytopenia suggestive of thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS). Injury to the endothelial substructure early in the post-transplant setting can be attributed to high-dose chemotherapy, radiation, or cytokine production in acute GVHD. Calcineurin inhibitors used for GVHD prophylaxis (cyclosporine or FK506) are directly toxic to the endothelium and can cause thrombosis in the microvasculature [57–62]. Sirolimus is a lactone antibiotic with a different mechanism of immunosuppression. Although this agent is not directly toxic to endothelial cells when used in combination with calcineurin inhibitors, it seems to potentiate vascular toxicity. Inflammatory cytokines [tumor necrosis factor (TNF) and interleukin-8 (IL-8)] released by tissue injury associated with GVHD have been linked to increases in prothrombotic events such as increases in tissue plasminogen activator and ultralarge von Willebrand factor assembly; IL-6 inhibits ultralarge von Willebrand factor cleavage [58,59]. The role of complement activation by the classical pathway was demonstrated by C4d deposition in renal biopsies of children with post-HCT TMA by Laskin et al. [63]. The involvement of the alternative pathway has been implicated by the detection of a high frequency of deletions of complement factor H (CFH) related genes 1 and 3 (83%) in children with post HCT TMA in both the autologous and allogeneic setting compared with the normal population (24%)and the presence of autoantibodies generated against complement factor H (CFH) in allogeneic recipients [64]. The incidence of TMA has varied widely from low levels of less than 1% for autologous HCT to as high as 70% in some small series of allogeneic HCT [65–69]. In contrast to idiopathic sporadic TTP/HUS syndrome, there is no defining laboratory marker such as ADAMTS13 deficiency, decrease in large von Willebrand multimers, or markers of complement activation that defines this entity or separates it from coexisting post-transplantation complications [65,70–72]. In a 2004 literature review of 447 cases of post-transplantation TMA culled from more than 5400 transplant procedures in 35 articles, George et al. reported an overall incidence of 8.2% with the majority of cases occurring within the first 3 months after HCT [73]. However, the criteria used to define the syndrome differed in 28 of these series and included a range of clinical settings from non-transfusion-dependent anemia with schistocytes and mild renal impairment to severe anemia, thrombocytopenia with dialysis-dependent renal failure, and/or neurologic symptoms that usually were manifested as confusion or seizures. In 2005, the Bone Marrow Transplant Clinical Trials Network (BMT CTN) established criteria for classifying and grading TMA; in 2007, the European BMT International Working Group (EBMT IWG) proposed slightly different criteria [74,75] (Table 78.3). Although there is a substantial degree of overlap, the CTN criteria that emphasize organ dysfunction capture a cadre with clinically worse features whereas the IWG, which focuses more on the thrombocytopenia and hemolysis, will include a broader range of endothelial cell injury. Thus reported outcomes will vary depending on the criteria used to define TMA in a series [76]. In 2008, shortly after both of the above criteria were published, Cho et al. reported on the impact of TMA in patients with acute GVHD (greater than grade II) [77]. Over a 4-year period (2001–2005), 674 patients received allogeneic HCT primarily with ablative conditioning; 158 (28%) developed grade II or greater acute GVHD. TMA occurred in 43 (39.5%) of these patients, which was graded as definite if the patients had either renal or neurologic dysfunction (16 patients) or probable if they had increased LDH and schistocytes and a negative Coombs test (27 patients). The median onset of recognition of TMA was 53 days (range 10–108 days) and GVHD was already present in 77% of the patients at the time. Twenty seven of the TMA patients died; TMA was considered a contributing factor in 11/13 of definite cases and in only 4/14 probable cases of TMA [77].

Table 78.3 BMT CTN Toxicity Committee consensus criteria [74] and EBMT IWG criteria [75] for TMA

BMT CTN criteria	IWG criteria
1. RBC fragmentation and more than two schistocytes per high-power field on peripheral smear	1. Increased percentage (>4%) of schistocytes in peripheral blood
2. Concurrent increased serum LDH above institutional baseline	2. De novo prolonged or progressive thrombocytopenia (PLT count thrombocytopenia <50×10^9/L or a 50% decrease from previous counts)
3. Concurrent renal[a] and/or neurologic dysfunction without other explanations	3. Decrease in hemoglobin concentration or increase in blood transfusion requirement
4. Negative direct and indirect antiglobulin test results	4. Decrease in serum haptoglobin concentration

[a] Doubling of serum creatinine from baseline (baseline = creatinine before hydration and conditioning) of 50% decrease in creatinine clearance from baseline.

The median time of onset of TMA in other adult allogeneic HCT series is 47 days, although an earlier onset at a median of 25 days was reported by Cutler et al. in patients receiving a combination of sirolimus and tacrolimus [78–80]. A series from St. Jude's Hospital in Memphis, TN, showed a 9.6% incidence of TMA with a much later onset of 171 days for pediatric patients; however, in this population T-cell depletion was used as a component of GVHD prophylaxis for all unrelated or mismatched related donor GVHD prophylaxis. In this report, T-cell depletion was identified as a risk factor for developing TMA rather than either acute GVHD or URD status, which are the major risk factors for TMA in adults [81]. In addition to grade II–IV GVHD, female gender, receipt of an unrelated donor product, and diagnosis of lymphoid malignancy were the major predisposing factors for TMA in a review of over 1200 patients treated at the M.D. Anderson Cancer Center using tacrolimus-based GVHD prophylaxis [82]. The incidence of TMA in this group was 5.9% compared with a 10.8% incidence using tacrolimus and sirolimus in the series reported from Dana Farber Cancer Institute in Boston, MA. The TMA rate for the CSP-based control group in the Dana Farber series was 4.2% [78]. The use of RIC has not led to a lower incidence of TMA with an incidence of 15–23% in three small series; in several of these cases, however, these patients had had a prior myeloablative HCT often within the previous 6 months [80,83,84]. In the M.D. Anderson report, which included more than 500 RIC recipients, the risk of TMA was equivalent to that for high-dose conditioning recipients. In 2010, investigators at the City of Hope Cancer Center (COH) reported on their experience with tacrolimus/sirolimus in 85 patients; over half of the patients (46) received RIC, 28 received fractionated total body irradiation (FTBI)/etoposide and 11 received busulfan plus cyclophosphamide. TMA developed in 7% of the RIC patients, 25% of the FTBI patients, and 55% of the busulfan recipients. The median tacrolimus levels were higher in the busulfan recipients than the other groups. Acute GVHD (greater than grade II) developed in 43% overall and was present in 75% of patients who subsequently developed TMA. Treatment for TMA was primarily dose reduction or discontinuation of one or both drugs. Only one patient received plasma exchange. TMA was reversible in all cases and only one patient required dialysis [85]. In a more recent COH follow-up of 177 patients who received tacrolimus and sirolimus for GVHD prophylaxis, the group had a 17% incidence of definite TMA with an additional 5% of patients with probable TMA with a median onset of TMA at 4.6 weeks. Acute GVHD was a pre-existing condition in 81% of these patients. Risk factors for TMA were myeloablative conditioning, grade II or greater acute GVHD and a sirolimus level of 9.9…ng/mL at day 14. In this series, TMA was a negative predictor for non-relapse mortality with a 33% non-relapse mortality at 2 years for patients with TMA versus 12.25% for those without TMA [86].

Therapy for post-HCT TMA

Patients who exhibit grade I TMA by NCI common toxicity criteria for TMA actually do not meet the current CTN definition of TMA (Table 78.4) However, these patients may represent a population in which attention to factors that may increase endothelial damage and RBC fragility may lessen the risk of evolution to overt TMA. Strategies include optimizing anti-hypertensive therapy, adjusting CSP, FK506, and sirolimus levels to lower therapeutic levels in patients without active GVHD, and providing appropriate magnesium replacement. In patients with renal dysfunction or neurologic abnormalities, discontinuing CSP or FK506 for a few days may help distinguish TMA from drug-related toxicity. However, a significant number of TMA patients also have active GVHD of grade II or greater that requires ongoing therapy. In the M.D. Anderson series, FK506 was continued at reduced doses in the majority of patients and discontinued only for severe renal or neurologic impairment. In patients requiring discontinuation of FK506, either steroids were started or the dose was increased to provide additional coverage for GVHD.

The majority of patients (95%) in the M.D. Anderson trial also received plasma exchange on a daily basis with tapering of exchanges based on clinical response [82]. Resolution of TMA-associated clinical and laboratory findings occurred in 60% of patients at a median of 29 days in this report, in contrast to much lower responses to plasma exchange (18–30%) in earlier series. Mortality, however, remained high with only 50% of the responders and none of the non-responders alive at 6 months. Control of GVHD and infection appeared to be crucial for long-term survival post-TMA. Ultimately, only 11/66 plasma exchange recipients were long-term survivors at 3 years post-HCT, comparable to the 70–95% mortality in other post-HCT TMA series, and in contrast to survival of >60% in idiopathic non-HCT TMA treated with plasma exchange [87–97]. Based on these experiences plasma exchange is less commonly employed for long-term management of TMA; its role is now more often only in the setting of significant organ dysfunction as a temporizing strategy as some patients may show improvement in neurologic or renal function early following plasma exchange. Mechanistically, plasma exchange either alone or in combination with rituximab might be helpful in (1) rapidly removing toxic levels of the inciting drugs or (2) depleting autoantibodies in the minority of cases which either led to defective cleaving of large von Willebrand multimers or indirectly led to complement activation. If there is not meaningful improvement in organ function within the first 5–7 days, plasma exchange should be stopped. New treatment approaches need to be developed for this entity. One of the novel treatments being explored is the use of eculizumab, the monoclonal antibody against the C5 component of complement, which was original approved for the treatment of paroxysmal nocturnal hemoglobinuria (PNH) and has more recently been given expanded utilization in the treatment of atypical hemolytic uremic syndrome (aHUS). There has been a case report in an adult and one small series of six children with severe post-HCT TMA treated with eculizumab [98,99]. In the pediatric series, four of six patients responded with improvement of hematologic parameters within 15–45 days; they were able to discontinue the drug after 4–13 doses. Drug levels and efficacy of complement blockade (as measured by a CH50 of ≤4) were tested twice weekly. While the routine treatment schedule was weekly, those without therapeutic levels of eculizumab received additional drug at the time the low target dose became available. Two children who had grade IV GVHD and multiorgan failure at the start of therapy never achieved evidence of adequate complement blockade and died of GVHD/TMA. CH50 levels <4 correlated well with therapeutic drug levels and are a much more easily available way to monitor suppression of complement activation outside the research setting. All patients received antibiotic prophylaxis for meningococcal infection throughout therapy.

Table 78.4 NCI common toxicity criteria for BMT-associated TMA

Thrombotic microangiopathy	Version 3.0
Grade I	Evidence of RBC destruction (schistocytosis) without clinical consequences[a]
Grade II	–
Grade III	Laboratory findings present with clinical consequences (e.g. renal insufficiency, petechiae)
Grade IV	Laboratory findings and life-threatening or disabling consequences (e.g. CNS hemorrhage/bleeding or thrombosis/embolism or renal failure)

[a] Must have microangiopathic changes on blood smear (e.g. schistocytes, helmet cells, red cell fragments).

Conclusion

As the scope of HCT evolves to encompass wider age ranges, differing sources of hematopoietic cells, newer conditioning regimens, and alternative immunosuppressive agents, we need to be conscious that changes in the kinetics of chimerism or the introduction of new drugs to either conditioning or GVHD prophylaxis and treatment can have a significant impact on the incidence and timing of hemolysis post-allogeneic HCT. A transplant program should develop a process and standard to define policies in transfusion support for ABO-incompatible transplant recipients, in post-ABO-incompatible product collection manipulations, and in pre- and post-transplant patient monitoring tests. It is important to maintain a high level of suspicion and to initiate appropriate testing for hemolysis of both immune and thrombotic etiologies in patients with unexplained anemia and increasing transfusion requirements. Better definition of TMA syndromes may allow earlier intervention, which should improve outcomes.

CHAPTER 79

Principles of Transfusion Support Before and After Hematopoietic Cell Transplantation

Jeffrey McCullough
University of Minnesota, Minneapolis, MN, USA

Introduction

Patients who are candidates for or are undergoing hematopoietic cell transplantation (HCT) have unique transfusion requirements. These are due to the need to minimize the likelihood of alloimmunization, the severe immunosuppression that these patients undergo, their temporary inability to produce blood cells, and the fact that their blood type may change and they may become a temporary or permanent chimera. Hence an effective blood bank and transfusion medicine program are essential for a successful HCT program.

Red blood cell components

Red cells

Red blood cells (RBCs) are the cells that remain after most of the plasma has been removed from whole blood. This blood component is often called "packed red cells" or "packed cells." The unit of red cells has a volume of about 350 mL, and will contain about 200 mL of red cells with a hematocrit of about 60%. The fluid portion of the unit is primarily an additive solution preservative used to enable red cells to be stored for 42 days. About 20 mL of plasma remains from the original unit of whole blood. One unit of red cells will increase the hemoglobin and hematocrit in an average-sized (70-kg) adult by about 1 g/dL and 3%, respectively. Red cells are the component of choice for any patient with severe anemia. Most patients who require red cell replacement do not also need intravascular volume replacement because anemia has developed slowly. Therefore, almost all transfusions given for red cell replacement are packed red cells, and whole blood is rarely used.

Red cell transfusions are usually given to HCT patients because of anemia. Although the decision to transfuse is usually based on the hemoglobin level, other clinical factors should also be considered. Most patients with hemoglobins of 10 g/dL or above do not require transfusion, and most patients with a hemoglobin of less than 7 g/dL will benefit from transfusion [1–5], and this is generally used as the indication for red cell transfusion. Because of the heterogeneity of patients, the clinical condition of the patient is of primary importance, and patients should not be transfused based only on their hemoglobin level. Patients with cardiovascular disease may benefit from transfusion at hemoglobin of 9 g/dL [4,5].

When there is acute blood loss, the major threat to the patient is the loss of intravascular volume and resultant cardiovascular collapse. In most "normal" patients, the loss of approximately 1000 mL of blood can be replaced by colloid or crystalloid solutions alone. An otherwise healthy individual can tolerate the loss of up to half of the red cell mass without the need for replacement. Because many patients have some degree of cardiovascular compromise, they will require red cell replacement after smaller volumes of blood loss.

Leukocyte-reduced red cells

Red cell and platelet blood components contain leukocytes that can alloimmunize transfusion recipients, leading to multiple problems (Table 79.1). In order to avoid these problems, leukocytes are removed from the red cells. This is done at the time of blood processing using filters that remove about 99.9% of the leukocytes leaving fewer than 5×10^6 per unit. In the past, filtration was performed at the bedside, but currently this is done in the laboratory in order to obtain more consistent leukocyte removal and prevent the accumulation of cytokines produced by the contaminating leukocytes.

The indications for leukocyte-reduced red cells are as follows:

- prevention of alloimmunization to leukocytes and platelets;
- prevention of transmission of cytomegalovirus (CMV) (see later);
- treatment of patients with multiple febrile transfusion reactions;
- prevention of immunomodulatory effects of transfusion (see later).

The kinds of patient who should receive leukocyte-reduced red cells include any individuals with a disease that can potentially be treated by HCT and those who will receive multiple transfusions during their life, such as patients with hemoglobinopathies (Table 79.2). In addition to alloimmunization to leukocytes, transfusion has other immunologic effects, generally referred to as transfusion-related immune modulation [6–8]. Because the clinical situations in which leukocyte-reduced blood components are valuable continues to increase, many blood centers and some countries now leukocyte-reduce all of their blood components [9,10].

Washed red cells

Washed red cells are red cells suspended in an electrolyte solution. Most plasma, platelets, and leukocytes have been removed, although leukocyte removal is not as complete as with frozen deglycerolized red cells. After washing, the red cells can be stored for only 24 hours

Table 79.1 Adverse effects of leukocytes in blood components

- Immunologic effects
  - Alloimmunization
    - Febrile non-hemolytic transfusion reactions
    - Refractoriness to platelet transfusion
    - Rejection of transplanted organs
  - Graft-versus-host disease
  - Transfusion-related acute lung injury
  - Immunomodulation
    - Increased bacterial infections
    - Increased recurrence of malignancy
- Infectious disease
  - Cytomegalovirus
  - Human T-lymphotrophic virus-I
  - Epstein–Barr virus

Table 79.2 Clinical situations in which leukodepleted red cells are recommended

- Hematopoietic stem cell recipients
- Acute leukemia
- Chronic leukemia
- Congenital platelet function abnormalities
- Congenital immune deficiency syndrome
- Hematologic malignancies potentially treated with stem cell transplantation
- Solid tumors potentially treated with stem cell transplantation
- Intrauterine transfusions
- Exchange transfusion for hemolytic disease of the newborn
- Hemoglobinopathy or thalassemia

because of the possibility of bacterial contamination. Since the major advantage is the removal of the plasma by washing, washed red cells are indicated for patients who have severe reactions caused by plasma.

Coagulation factor components

Fresh frozen plasma

Fresh frozen plasma (FFP) is plasma separated from whole blood and placed at −18°C or lower within 8 hours of collection. The unit of FFP has a volume of about 200–250 mL and contains all of the coagulation factors that are present in fresh blood. FFP is not considered to contain red cells and is usually administered without regard to Rhesus (Rh) type. However, occasional rare reports have suggested that units of FFP contain a small amount of red cell stroma that can cause immunization to red cells. Because the plasma contains ABO antibodies, the plasma must be compatible with the recipient's red cells.

Although FFP has been widely used for years and its use is increasing, there have been few good clinical trials to establish its efficacy [11]. The generally accepted indications for FFP [12] are documented coagulation factor deficiencies for which factor concentrates are not available, especially factor V, multiple factor deficiencies such as patients with severe liver disease or anticoagulated with warfarin, and massive transfusion. FFP is used as the replacement solution for plasma exchange in patients with thrombotic thrombocytopenic purpura, but it is not indicated for use as a volume expander or a nutritional source.

Bleeding due to dilution of multiple coagulation factor deficiency can occur in massive transfusions. This dilution occurs because red cell components contain little plasma. It is important to replace coagulation factors in platelets before coagulopathy develops [13,14]. Most hospitals have established massive transfusion protocols in which a standard combination of packed red cells, thawed plasma, and platelets is provided by the blood bank very quickly [15]. There is debate about the best ratio of the three components, but 1: 1: 1 is most often used. Patients who are undergoing massive transfusion may also develop disseminated intravascular coagulation (DIC) [16] because of the severity of the underlying problem. Thus, a bleeding diathesis may develop that is a combination of the dilutional coagulopathy of massive transfusion and the "consumption coagulopathy" of DIC.

In mild forms of DIC, transfusion is usually not necessary. However, in the more extreme forms, there is usually a deficiency of factors V and VIII, fibrinogen, and platelets. Replacement of coagulation factors in the management of DIC should be based on laboratory abnormalities and not on arbitrary formulas. When replacement is necessary, FFP is usually used to replace all factors. Coagulopathy may also develop in patients undergoing HCT. The use of FFP as prophylaxis for patients with coagulopathy who are to undergo invasive procedures is discussed later in this chapter.

Plasma (FP24)

Plasma separated from whole blood between 8 and 24 hours after collection can be frozen, stored for up to 1 year, and used as a source of coagulation factor replacement, but FP24 contains only 50–75% of factors V and VIII. This plasma product can be used in most situations requiring replacement of multiple coagulation factors and is gaining wider use.

Cryoprecipitate and fibrinogen

Cryoprecipitate is the cold-insoluble portion of FFP that has been thawed between 1 and 6°C. It is stored at −18°C or below and can be kept for up to 1 year. Cryoprecipitate contains coagulation factor VIII, fibrinogen, and von Willebrand factor. Each bag of cryoprecipitate contains about 250 mg of fibrinogen, and this is now its major use. Cryoprecipitate is not a suitable source of coagulation factors II, V, VII, IX, X, XI, or XII. Virally inactivated fibrinogen concentrate prepared from human plasma is now available. It is recommended when the fibrinogen level is <100 mg/dL, although in acute blood loss, transfusion at a level of 150 g/dL is being used. The US Food and Drug Administration (FDA)-approved indication is limited to congenital fibrinogen deficiency, but it is being used in other situations [17], especially in Europe.

Blood group compatibility of components used to replace coagulation factors

FFP need not be ABO-identical but should be compatible with the recipient's red cells and can be given without regard to Rh type. Red cell compatibility testing is not necessary. Cryoprecipitate should also be administered as ABO compatible with the recipient. Although the volume of each unit is small, most therapy involves many units, hence the total volume of plasma may be large. Cryoprecipitate can be administered without regard to Rh type. Compatibility testing is not necessary. In HCT, patients' cryoprecipitate is usually used to replace fibrinogen, but the recipient's fibrinogen may become elevated by the fibrinogen contained in cryoprecipitate if many units are given to patients who are not hypofibrinogenemic.

Platelet components

Platelet concentrates prepared from whole blood

Platelet concentrates, often referred to as "random-donor" platelet concentrates, are prepared by centrifugation of whole blood. The centrifugation technique used in Europe and Canada differs from that used in the United States [18]. At least 75% of the units of random-donor platelets must contain at least 5.5×10^{10} platelets.

Most units contain 6–8 × 10^{10} platelets, and each blood bank should be able to provide an estimate of the platelet content from their quality control data. To achieve a therapeutic dose, platelets from 4–5 units of whole blood are pooled.

Platelet concentrates prepared by apheresis

Several different instruments that separate the platelets using centrifugation are available for the collection of platelets by apheresis. The instrument operation is controlled by a microprocessor that regulates the blood flow rate, the anticoagulant added to the whole blood entering the system, the centrifuge conditions, the component separation, and recombination of the remaining components that are then returned to the donor.

The official name of this component is "platelets, pheresis," but it is usually called single-donor platelet or plateletpheresis concentrate. For quality control purposes, a unit or bag of plateletpheresis concentrate must contain at least 3 × 10^{11} platelets in a minimum of 75% of the units tested, but most plateletpheresis concentrates contain approximately 3.5–4 × 10^{10} platelets. Plateletpheresis usually requires about 1.5 hours and involves processing 4000–5000 mL of the donor's blood through the blood cell separator. Platelets obtained by plateletpheresis are processed, tested, and labeled the same as whole blood. This includes ABO and Rh typing, and required testing for all transfusion-transmitted diseases. The number of platelets contained in each concentrate is determined, although this information may not necessarily be recorded on the label. Each platelet concentrate has a volume of approximately 200 mL and contains very few (0.5 mL) red cells, so that red cell cross-matching is not necessary. The white blood cell (WBC) content varies depending upon the instrument and technique used for collection, but platelet concentrates produced by apheresis are usually considered to be leukocyte reduced and contain fewer than 5 × 10^6 leukocytes.

Platelet storage conditions and duration

Platelets are stored at 20–24°C to maintain functional effectiveness for 5 days [19]. The variables that affect the quality of platelets during storage include the temperature, anticoagulant preservative solution, storage container, type of agitation, and volume of plasma [19,20]. Citrate phosphate dextrose and citrate phosphate dextrose–adenine solutions are satisfactory platelet preservatives; undisturbed storage is inferior to gentle agitation, and horizontal agitation is preferable to end-over-end agitation. The composition, surface area, and size of the storage container influence the ability for carbon dioxide to diffuse out and oxygen to enter the platelet concentrate, and storage containers specifically designed to optimize platelet quality are now used routinely.

Maintenance of the pH above 6.0 is crucial for satisfactory platelet preservation. This combination of storage container, agitation, preservative solution, temperature, and the use of about 50 mL of plasma provides satisfactory preservation of platelets for 5 days. An electrolyte platelet additive solution used in Europe is now licensed in the United States. This replaces most of the plasma and is associated with fewer allergic transfusion reactions.

Transfusion of platelets

The decision whether to transfuse platelets depends on the clinical condition of the patient, the cause of the thrombocytopenia, the platelet count, and the functional ability of the patient's own platelets. Most platelets are transfused to patients with transient thrombocytopenia due to chemotherapy for malignancy or those undergoing HCT [21]. Most platelet transfusions are used for the prevention of bleeding (as prophylaxis) rather than the treatment of active bleeding [21].

Very few controlled studies of prophylactic platelet transfusion were carried out when platelet therapy first became available. Some studies supported the use of prophylactic transfusions, but other studies were not able to show a benefit of prophylactic platelet transfusion [22]. Two recent studies compared prophylactic transfusion with transfusion only after bleeding occurred. Wandt et al. [23] concluded that prophylactic transfusions were not necessary, whereas Stanworth et al. recommended prophylactic transfusion, especially for patients with acute myeloid leukemia (AML) [24]. Despite the lack of substantial convincing clinical trial data, it became common practice for physicians to use platelet transfusions to prevent serious bleeding when the platelet count was less than 20,000/μL, because there is little risk of serious spontaneous hemorrhage when the platelet count is more than 20,000/μL, but the risk increases with lower counts [25,26]. In stable thrombocytopenic patients, there is no increase in stool blood loss at platelet counts of 10,000/μL, and blood loss increases only when the platelet count reached 5000/μL [27].

Experience in the management of thrombocytopenic patients has made it possible to maintain patients at lower platelet counts than were previously believed to be safe. Serious bleeding usually occurs only when the platelet count is below 10,000/μL, and fatal bleeding is unlikely to occur at platelet counts above 5000/μL. Gmur et al. [28] found that the threshold for prophylactic platelet transfusion could be 5000/μL in uncomplicated patients, 10,000/μL in individuals with fever or bleeding, and 20,000/μL in patients with coagulopathy or bleeding sites. Heckman et al. [29] found no difference in red cell use, days of fever, hospitalization, thrombocytopenia, remission, death, or major bleeding complications when prophylactic transfusion thresholds of 20,000 and 10,000/μL were compared.

Rebulla et al. [30] reported that, in patients with acute leukemia undergoing first induction of remission, there was no difference in deaths, red cell transfusions, or severe hemorrhage, but there was a 21.5% reduction in platelet use using a transfusion threshold of 10,000/μL compared with 20,000/μL. Wandt et al. [31], summarizing experience in 17 centers in Germany, found no difference in bleeding complications when 10,000 or 20,000/μL thresholds were used, and hemorrhagic deaths actually occurred in two patients with platelet counts of 36,000 and 50,000/μL. In stable marrow transplant recipients, lowering the transfusion threshold from 20,000 to 10,000/μL did not increase severe bleeding or deaths due to bleeding [32], but reduced platelet use by about 25%. Aderka et al. [33] proposed, based on an analysis of 196 patients with acute leukemia, that prophylactic platelet transfusion was not necessary when the platelet count was above 10,000/μL. More recently, Zumberg et al. [34] reported no differences in the incidence or severity of bleeding in 159 HCT patients prospectively randomized to receive platelet transfusions at a threshold count of 20,000 or 10,000/μL. A National Institutes of Health Consensus Conference recommended that the 20,000/μL value traditionally used for prophylactic platelet transfusion could be safely lowered for many patients [35]. Beutler [36] recommended lowering the indications for prophylactic platelet transfusion, and now many physician and hospital guidelines use platelet counts of 10,000 or 5000/μL as the indication for prophylactic transfusion to patients with uncomplicated conditions [37].

Establishing the indications for platelet transfusion remains complex because many studies are not powered to show modest differences, most do not use bleeding as the end-point, and the patient population is heterogeneous. The guideline of a platelet count of 10,000/μL for prophylactic transfusion applies to the stable, uncomplicated patient. However, many HCT patients are febrile, have severe mucosal bleeding, or have other complications that necessitate transfusion at higher platelet counts [21]. Clinical decisions to increase the transfusion threshold are variable and do not coincide with a rigidly controlled bleeding assessment [38].

Treatment of active bleeding

Platelet transfusions are not necessary for bleeding patients with a platelet count above 100,000/μL because they have a normal bleeding time. With platelet counts below 100,000/μL, the bleeding time is increasingly prolonged [39]. The optimum platelet count to achieve in a bleeding patient is not known. In one study [40] of patients undergoing surgery, prophylactic platelet transfusions were given to those whose platelet count was less than 50,000/μL. Bleeding was similar in patients with levels less than 50,000/μL who received platelet transfusion compared with those whose platelet count was above 50,000/μL and who did not receive platelet transfusion. The bleeding did not relate to the platelet count but instead to the severity of the surgical procedure. Thus, in actively bleeding patients, platelet transfusion should be considered in those with a platelet count of less than approximately 50,000/μL. An attempt to achieve a level of above 50,000/μL is recommended. If the patient's platelets are dysfunctional due to causes such as drugs or uremia, the bleeding time may be much longer than would be expected based on the degree of thrombocytopenia. In those situations, the decision to give a platelet transfusion is made on clinical grounds alone.

Dose of platelets and outcome of platelet transfusion

There is a dose–response effect from platelet transfusion. Within 1 hour after transfusion, the platelet count increases by approximately 10,000/μL when 1×10^{11} platelets are transfused into a 70-kg patient [41]. Since a transfusion usually contains approximately $3.5–4.0 \times 10^{11}$ platelets, the platelet count should increase by 35,000–40,000/μL in an average-sized adult. In order to achieve these increases in platelet count, four to six whole-blood-derived platelet concentrates are pooled or one apheresis product is used. For some individuals, the volume of plasma in the final pooled component is too large, and plasma must be removed before transfusion. The loss of platelets during this concentration step is reported to be from 15% to as much as 55% [42]. Although concentration or volume reduction of pooled platelets can be carried out successfully, and is often done for small patients or those who are receiving large volumes of blood components or intravenous fluids, some platelets are lost in the process.

The 1-hour post-transfusion platelet count is one predictor of an effective platelet transfusion [41]. If a very accurate determination of the response to platelet transfusion is needed, the 1-hour corrected count increment (CCI) or the percentage recovery can be determined. This takes into account the number of platelets transfused and the size of the patient. The CCI is calculated as follows:

$$\text{CCI} = \frac{(\text{post-transfusion} - \text{pre-transfusion platelet count}) \times (\text{body surface area})}{\text{No. of platelets transfused}}$$

The expected CCI is about 15,000/μL × 10^{11} platelets transfused per square meter of body surface area. If the CCI is less than 5000–7500, the patient is considered to be refractory. If platelet recovery is used as an indicator, the expected result is about 65% because some of the platelets normally are sequestered in the spleen.

It has been suggested that frequent transfusions of a lower dose of platelets will reduce the number of platelets needed [43]. Conversely, when larger numbers are transfused, the time between transfusions is extended [44,45], suggesting that overall fewer platelets or transfusions might be needed. A multi-center trial involving 1272 patients established that transfusion of half or twice the current standard dose of platelets was equally effective as the standard dose [26]. The likelihood of bleeding was similar for platelet counts ranging from 5000 to 80,000/μL, but there was a difference in number of transfusions. Children in this clinical trial had a higher rate of bleeding than adults, but the platelet dose did not affect bleeding [46]. A small study of platelet dose in adults was halted prematurely because of non-statistically significant but clinically important bleeding in the low-dose group [47]. Despite the large, well-performed study [26], transfusion practice has not generally changed to the use of lower doses of platelets.

ABO (H) and Rh in platelet transfusion

ABO antigens are intrinsic to the platelet, and some are also adsorbed on its surface. When ^{51}Cr-labeled group A platelets are transfused to normal group O volunteers, the recovery is reduced [48], and the higher the ABO isoagglutinin titers, the greater is the reduction in recovery of transfused platelets. This ABO effect has been substantiated clinically in several studies. There is a reduced recovery when platelets from human leukocyte antigen (HLA)-matched donors are transfused to alloimmunized patients who are ABO incompatible with the donor platelets [49], and blood group O patients may be refractory to platelets transfused from group A donors but not from platelets transfused from group O donors [49]. Two other studies substantiated the concept that if platelets that contain ABH antigens are transfused into patients with circulating antibody directed against those antigens, the intravascular recovery of the transfused platelets is substantially decreased [50,51]. Decreased recovery of transfused platelets also occurs when the incompatibility involves transfusion of ABO antibody directed against the recipient's ABO antigens (e.g. group O platelets transfused to a group A patient) [51]. This may be due to the formation of circulating immune complexes by soluble ABH substance and ABO antibodies, and can occur with the antigen–antibody complexes from either donor or recipient antibody and donor or recipient ABH substance. Although ABO incompatibility is associated with reduced post-transfusion platelet recovery, this is not of a magnitude that would contraindicate transfusion of ABO-mismatched but HLA-matched platelets.

A separate consideration involving the ABO system and platelet transfusion is the potential administration of large volumes of ABO-incompatible plasma (e.g. group O platelets transfused to group A patients) to cause red cell hemolysis. Most institutions have a policy to avoid or limit the amount of ABO-incompatible plasma transfused in platelet products [52]. Limiting the volume of ABO-incompatible plasma that a patient can receive can be in terms of a percentage of the patient's estimated blood volume or an absolute volume limit or by using only a low ABO titer (<1: 200) for incompatible transfusion. As mentioned earlier, the platelet product can be concentrated further by removing some of the plasma.

Rh antigens are not present on the platelet surface. However, the few red cells contained in the platelet concentrate can lead to immunization, hence Rh must be considered in platelet transfusion. In Rh-negative cancer patients, reported rates of immunization to the D antigen range from 0% to 18% [53–56]. Because oncology patients and HCT recipients receive a large number of platelet transfusions, it is usually not possible to provide all Rh-negative platelets for Rh-negative patients. Rh immune globulin can be administered to prevent alloimmunization, but this is not usually done and is not recommended. Even when circulating anti-D develops, this antibody does not interfere with the circulation of Rh (D)-positive platelets [57]. If Rh immune globulin is to be administered to prevent alloimmunization, the dose of Rh immune globulin can be determined from the number of units of platelets that the patient receives. For instance, since most therapeutic doses of platelets (e.g. one single-donor unit or four to five pooled random-donor units) contain less than 1 mL of red cells, one standard dose of 300μg of Rh immune globulin is sufficient [54].

Lack of response (refractoriness) to platelet transfusion

Many patients do not attain the expected post-transfusion increment in platelet count and are said to be "refractory" to platelet transfusion. In patients who receive large numbers of platelet transfusions, the CCI may decrease for reasons that are not well understood [58]. Refractoriness to platelet transfusion can be caused by factors related to the patient and/or factors related to the platelet concentrate.

Factors related to the patient

In patients who have HLA or platelet antibodies, such as those with autoimmune thrombocytopenic purpura or patients who are immunized to antigens of the HLA system, survival of circulating platelets is extremely brief, sometimes only a few minutes [59]. Splenomegaly also causes sequestration of platelets and a reduced post-transfusion increment [59]. Factors associated with a poor response to platelet transfusion include DIC, amphotericin administration, palpable spleen, presence of HLA antibody, presence of platelet antibody, and fever [60]. It is not clear whether active bleeding is associated with a reduced response to platelet transfusion.

Hence patients can be refractory due to alloimmunization (HLA and/or platelet antibodies) or non-immune clinical factors. In some patients, refractoriness is clearly associated with the presence of HLA antibodies; however, many of these patients also have one or more clinical factors present, which could account at least partially for the refractoriness, and non-immune factors may be the major cause of refractoriness [38,61,62]. Therefore, in practice, it is very difficult to determine whether a patient is refractory due to immune or non-immune factors, and this affects the strategy used to manage these patients. In the past, the incidence of refractoriness was rather high, but during the 1990s it was only about 15% after the first 8 weeks of therapy [63]. This decrease may be due to changing transfusion practices, described in the section on prevention of alloimmunization, or to more intensive chemotherapy.

Factors related to the platelet concentrate

ABO incompatibility can reduce the intravascular recovery and survival of transfused platelets. Transfusion of platelets near the end of their storage period can also reduce recovery [64]. Transfusion of similar numbers of apheresis- or whole-blood-derived platelets should give similar increments in platelet count. There is no reason to believe that transfusion of whole-blood-derived platelets could give the misleading impression of refractoriness due to poor increments based only on the source of the platelets.

Strategies for managing patients who are refractory to platelet transfusion

HLA matching for platelet transfusion

If the use of ABO-matched platelets stored for the shortest time feasible fails to produce a satisfactory increment, transfusion of either HLA-matched or cross-matched platelets should be attempted. Platelets from HLA-identical siblings, HLA-identical unrelated donors, and even partially matched donors can provide a good post-transfusion response [65]. However, most HLA-matched platelets obtained from unrelated donors have some antigens mismatched with the patient. Although the average response to these partially matched transfusions is similar to that from fully matched HLA-identical transfusions, about 30% of HLA-matched transfusions do not provide a satisfactory response [64]. Also, since these patients require frequent platelet transfusions, many donors who are matched with the patient must be available to sustain the patient for days or a few weeks, so that in practice it is often difficult to maintain a patient on HLA-matched platelets. A different approach with some success is to identify the HLA antibody specificity and select donors who lack the corresponding HLA antigens [65,66]. It is not clear whether this results in more successful transfusions.

Platelet cross-matching for platelet transfusion

Immune platelet refractoriness is usually due to HLA antibodies, but platelet-specific antibodies may also be involved. Therefore, one approach that might be effective in overcoming the 30% failure of HLA-matched transfusions is cross-matching the patient's serum and potential donor's cells. Several different platelet antibody methods have been used, and there was great variability in results, with the positive predictive value ranging from 73% to 100% and the negative predictive value from 52% to 92% in 10 studies summarized by Heal et al. [51].

The method currently in clinical use predicts a successful transfusion outcome in 97% of patients with no clinical factors to cause non-immune platelet destruction [67]. Successful prediction of transfusion response was confirmed by O'Connell et al. [68] and Friedberg et al. [69], who, in a separate study of 962 single-donor platelet transfusions to 71 refractory patients, showed that the solid-phase red cell adherence assay was superior to HLA matching. The relatively effectiveness of HLA matching versus cross-matching has not been established. In one study [70], HLA matching and platelet cross-matching provided similar degrees of successful 1-hour CCIs (40–60%). If only transfusions were used in which four HLA-A,B locus antigens were identical between donor and recipient (A match) or in which only three HLA-A,B locus antigens were identified in the donor, HLA matching was superior to platelet cross-matching. However, Moroff et al. [70] concluded that a similar number of successful transfusions could be obtained by either HLA matching or platelet cross-matching, and this is the general belief currently. A recent smaller study [62] also found no difference in the number of successful transfusions selected by HLA matching or cross-matching, although only about 25% of transfusions using either method were successful. It was suggested that in the more than 20 years since the previous studies, patients have become more complex and there are more clinical factors that overwhelm the immunologic matching/selection of platelets [62].

Other approaches to the refractory patient

Other strategies that have been attempted but are not usually successful and are not recommended include plasma exchange, treatment of the patient's plasma with a staphylococcal protein A column, cyclosporine, and intravenous immunoglobulin.

A practical approach to the patient who is refractory to platelet transfusion

The lack of a response to platelet transfusion is often associated with bleeding. These patients are usually quite ill, with problems such as fever, sepsis, DIC, or viral infections. Therefore, clinical factors such as infection that might cause refractoriness should be sought and, if they are present, appropriate treatment should be initiated. Depending on the patient's condition and the degree of concern about the platelet count, additional simple steps that can be attempted to improve the response to platelet transfusion include the transfusion of ABO-identical platelets and platelets stored for the shortest time feasible. The techniques for platelet transfusion should be reviewed to be sure the platelets are not being damaged or lost due to improper handling after leaving the blood bank, use of incorrect filters, or improper storage conditions. An additional step is to be certain that the platelet concentrates contain an adequate number of platelets, which can be done by checking the blood bank quality control testing results and the platelet count and content of the specific concentrates being used for the patient.

If these measures fail, platelets that are matched to the recipient should be used. This can be accomplished by HLA matching of donor and recipient, or by using platelets that are compatible in a cross-match.

Although either HLA matching or platelet cross-matching can be used to obtain about the same effect, one practical difference is that usually cross-matched platelets can be obtained more rapidly than HLA-matched platelet. Cross-matching is done on platelets already collected and available in inventory, whereas HLA-matched donors must be located and scheduled for donation. A suggested practical strategy for dealing with patients who are refractory to platelet transfusion is as follows:

- Treat any correctable clinical factors present that may cause platelet refractoriness. Until these factors have been eliminated, recognize that any of the steps listed below may not be effective.
- Ensure that the patient is receiving the correct dose of platelets.
- Give at least one test transfusion of platelets that are not more than 48 hours old.
- Ensure that platelets being transfused are ABO identical.
- If these steps have failed and transfusion is urgently needed, give transfusions of either cross-match-compatible or HLA-matched platelets, whichever is available soonest. Give at least one and preferably two or three such transfusions.
- If satisfactory platelet count increase is not obtained, the refractoriness is probably due to non-immune clinical factors and there is no value in continuing HLA-matched or cross-matched platelets.
- Determine whether the patient has HLA or platelet-specific antibodies, or both. This precaution may be of value in making future decisions about platelet transfusion if the patient does not respond to HLA-matched or cross-matched platelets.
- Determine whether the patient is receiving medications such as vancomycin that might cause drug-dependent antiplatelet antibodies. If so, carry out a drug–platelet antibody test.

Some patients do not respond to either HLA-matched or cross-matched platelets. Often these are patients with many complications. One approach is to increase the dose of platelets to two or even three single-donor, or 10–20 random-donor, units per day. Although this may enable physicians to feel that they are doing something helpful, usually the patients fail to achieve a substantial increase in platelet count. It is not known whether the transfusions are helpful despite the lack of increase in circulating platelets.

Prevention of alloimmunization and platelet refractoriness

Because of the difficulty in managing patients who are refractory to platelet transfusion, there is considerable interest in preventing alloimmunization. Immunization may be caused by pregnancy but is also due to the leukocytes contained in the platelet and red cell transfusions [71]. Although the exact mechanism of alloimmunization has not been defined, it appears that intact viable leukocytes present HLA class I and II antigens for processing [72]. Therefore, strategies to modify the transfusion products have been adopted. In general, these strategies have involved limiting the number of donor exposures, removing the leukocytes, or treating the components to render the leukocytes non-immunogenic.

There is a very substantial body of data that establishes that leukocyte reduction reduces the incidence of alloimmunization and delays and/or reduces the onset of refractoriness [73–75]. In a study of more than 500 newly diagnosed patients with acute leukemia [63], the use of leukocyte-reduced red cells and platelet concentrates reduced the incidence of alloimmunization, and no difference was found between pooled random-donor and single-donor platelet concentrates. This confirms that the important factor is the reduction of the leukocyte exposure rather than the number of different donors. Filtration of the components at the time they are produced in the laboratory is more effective than bedside filtration for prevention of alloimmunization because the leukoreduction can be standardized and controlled better [76].

Ultraviolet (UV) radiation inhibits the ability of lymphocytes to either proliferate or stimulate in a mixed lymphocyte culture, but UVB light does not interfere with platelet function in vitro or in vivo at doses that will abrogate lymphocyte function. In a large clinical trial, UVB-irradiated platelets reduced the incidence of alloimmunization to the same extent as leukoreduced platelets [63]. Therefore, although UVB light appears to be effective in preventing alloimmunization, it is not currently used, and no systems are licensed by the FDA for routine blood bank use. Pathogen inactivation (discussed later) uses UV light and may be effective in preventing alloimmunization.

Role of thrombopoietin in platelet transfusion

It was hoped that the long-sought platelet growth factor thrombopoietin (TPO)would reduce the need for platelet transfusions. TPO could influence transfusion therapy in HCT patients in at least two ways. It could be given to the patient in hope of speeding the recovery of platelet production and shortening the period of thrombocytopenia, thus reducing bleeding complications and the need for platelet transfusions. Alternatively, TPO could be given to platelet donors to elevate the donor's platelet count, and increase the number of platelets collected and transfused, in the hope of increasing the time between transfusions and reducing the number of donor exposures that the patient received.

In patients with advanced cancer, TPO increased the platelet count in a dose-dependent manner, elevated the nadir platelet count, shortened the period of thrombocytopenia, and decreased platelet transfusion requirements [77]. However, these observations have had little impact on platelet use because these patients did not receive many platelet transfusions. The response to TPO in HCT patients receiving myeloablative therapy is even less impressive. TPO therapy has not shorted the duration of thrombocytopenia or decreased the need for platelet transfusions [77], possibly because endogenous TPO levels are already very high in these patients, TPO receptors may be downgraded or TPO may actually inhibit the release of mature platelets from megakaryocytes. Because the many pluripotent functions of TPO have not been well studied, the reasons for its role or lack thereof in the HCT setting are not completely understood.

When a TPO-like agent was administered to normal plateletpheresis donors, the level of circulating platelets increased, and thus the yield of platelets following plateletpheresis increased 2-4-fold. When these high-dose concentrates were used as a single transfusion, they provided a larger increase in platelet count than present transfusions, prolonged the interval between transfusions, and reduced the number of donor exposures [44]. However, in separate studies, TPO inhibitors occurred in normal subjects, and development of that agent has been discontinued and no further efforts to use TPO-type agents in donors are under way.

Granulocyte concentrates and granulocyte transfusion

A series of studies in the 1970s established that granulocyte transfusions provided improved survival in patients with documented Gram-negative sepsis who remained granulocytopenic for at least 10 days (reviewed in [78]). Most clinical trials of granulocyte transfusion involve patients with Gram-negative bacteremia, there is little information regarding other organisms, and patients with fever of unknown origin do not experience improvement as a result of granulocyte transfusion. Other than bacteremia, the site of infection does not seem to correlate with response to granulocyte transfusion. Prophylactic granulocyte transfusions using doses available in the 1970s were not helpful [79].

A major reason for the limited effectiveness of granulocyte transfusions was thought to be the small dose of cells [80]. Hematopoietic growth factors such as granulocyte-colony stimulating factor (G-CSF) can be used to stimulate granulocyte production in normal blood donors, increasing the level of circulating granulocytes to about 30,000/μL with G-CSF alone and, by combining the use of corticosteroids and G-CSF, the level of circulating granulocytes can be increased to approximately 40,000/μL [80]. Leukapheresis of these donors results in a dose of up to $7–8 \times 10^{10}$ granulocytes [80]. G-CSF-mobilized granulocytes have normal in vitro function and migrate to sites of infection [80]. There have been several reports of the clinical use of G-CSF-mobilized granulocytes, but the studies were small or uncontrolled, involved different definitions or patient eligibility or prophylactic transfusions, or were in children where all doses were very high due to the patient's smaller size (reviewed in [78]). With the availability of high-dose granulocyte concentrates, low-dose concentrates obtained from donors stimulated with dexamethasone only are not recommended. A large, controlled, multi-center clinical study by the National Heart, Lung, and Blood Institute-funded Transfusion Medicine/Hemostasis Clinical Trials Network did not find a benefit to high dose transfusions except that the study was underpowered and many patients did not actually receive high dose granulocyte concentrates [81].

Transfusion strategies in HCT

Pre-transplantation

For a pre-transplant transfusion strategy, patients can be thought of as being in three groups: immunocompetent but not requiring transfusion, immunocompetent and requiring transfusion, and immunocompromised. An example of the first group is patients with inborn errors of metabolism, who rarely require transfusion before HCT. The other two groups of patients have a variable degree of immunocompetence and may become alloimmunized to leukocytes or platelets following transfusion. Alloimmunization may cause transfusion reactions but, more importantly, may interfere with engraftment in some patients. The presence of HLA antibodies is associated with marrow graft rejection [82]. Pre-transplant transfusions are associated with increased graft failure rates [83,84]. For immunocompetent patients such as those with aplastic anemia, hemoglobinopathies, or myelodysplastic syndrome who require pre-transplant transfusions, efforts should be made to prevent alloimmunization. Patients with aplastic anemia should be evaluated quickly and HCT, if indicated, should be performed as soon as possible to minimize the number of pre-transplant transfusions. Many of these patients can be managed safely when prophylactic platelets are given only when the platelet count is less than 5000/μL [85]. For patients such as those with hemoglobinopathies or myelodysplastic syndrome who require red cell or platelet transfusions before HCT, the following are recommended:

- Red cells should be depleted of leukocytes.
- Platelet concentrates should be depleted of leukocytes. This can be done by filtration or by certain apheresis collection procedures.
- The use of single-donor instead of pooled random-donor platelet concentrates should be considered. However, the largest study of this issue did not show a difference in the rate of alloimmunization between single-donor and pooled random-donor platelet concentrates [63].
- Family members should not be used as blood or blood component donors (before transplant) because of the risk of alloimmunization causing an unsuccessful marrow graft [85].

Patients with malignancies who will undergo HCT usually have received multiple transfusions during the initial chemotherapy of their underlying disease. However, the effects of this on subsequent marrow engraftment are not as severe as for patients with aplastic anemia because standard chemotherapy of their malignancy is extremely immunosuppressive. Hence transfusion therapy for these patients can be that necessitated by their chemotherapy. The increasing use of reduced-intensity preparative regimens may make engraftment more problematic in heavily alloimmunized patients. Therefore, red cells and platelets should be leukocyte reduced in order to minimize the possibility of alloimmunization. Transfusions from family members probably should be avoided [85]. Although one study showed no increase in graft failure in patients with leukemia who received transfusions from family donors [86], this is not generally recommended.

Post-transplantation

Because of the severe immunosuppression caused by the pre-transplant preparative regimen, fatal GVHD can occur as a result of transfusion of viable lymphocytes that are present in blood components. Transfusion-related GVHD can be prevented by irradiating all blood components with at least 2500 cGy (see below).

During the time between HCT and marrow engraftment, the return of production of different blood cell lines varies, so that although the duration of transfusion therapy may range from a few days to several weeks, the need for different components varies with different types of transplant. Almost all patients require platelet and red cell transfusions, but since HCT does not usually interfere with the production of coagulation factors, transfusion of FFP and cryoprecipitate is necessary only if coagulopathy develops. Although HCT patients are severely neutropenic, granulocyte transfusions are usually not necessary (see above).

Regular packed red cells are used and should be leukocyte reduced to minimize the likelihood of inducing alloimmunization. Either whole blood-derived or single (apheresis)-donor platelets can be utilized. Platelets should be leukocyte reduced to prevent alloimmunization. Results of studies of leukocyte-reduced platelet concentrates in situations other than HCT have indicated that this strategy is effective [73–75]. Leukocyte reduction can decrease platelet refractoriness even in patients who were already alloimmunized [63]. Although these studies of alloimmunization have not been carried out in HCT patients, the effectiveness of leukocyte reduction in other situations indicates that leukocyte-reduced platelets should be used in HCT patients.

If patients become refractory to platelet transfusion, HLA-matched unrelated or family donor platelets can be used (see above).

Transfusion prophylaxis for invasive procedures

Most patients will undergo placement of a central venous access line, and many may undergo other invasive diagnostic procedures such as lumbar puncture, bronchoscopy, thoracentesis, bone marrow aspiration, or even liver biopsy. At the time of these procedures, the patient may have abnormal coagulation test results or be thrombocytopenic. Unfortunately, there are insufficient clinical data to determine the value of prophylactic transfusion of FFP to correct coagulopathy [87] or platelet transfusion to increase the platelet count above an arbitrary level [88,89]. However, based on an extensive summary of experience, but in the absence of firm data, the American Society of Clinical Oncology has recommended that a platelet count of 40,000–50,000/μL “is sufficient to perform major invasive procedures” [89]. Bone marrow aspiration and biopsy can be carried out safely at platelet counts of >20,000/μL, liver biopsy >50,000, gastrointestinal endoscopy >20,000, bronchoscopy >20,000, transbronchial biopsy >40,000, and dental extractions and catheter insertions >50,000/mL [89].

Prevention of transfusion-transmitted CMV infection

CMV disease is an important source of post-transplant mortality (see Chapter 87). Most CMV infections in HCT patients occur in those with CMV antibody, and probably are due to reactivation of virus from a previous infection, not to acquisition of a new strain. However, in CMV antibody-negative patients who receive unscreened blood products, the risk of developing CMV infection is high. The likelihood of these patients acquiring CMV infection is almost eliminated by the use of CMV antibody-negative blood components [90,91] and much of the remaining CMV transmission may be due to the graft and it cellularity [92].

Because a substantial portion of blood donors are CMV antibody positive, providing CMV antibody-negative blood components is sometimes difficult. Although infectious viral particles cannot be recovered from normal donors previously infected with CMV who have antibodies to CMV, blood from these donors can transmit CMV. Because it is presumed that leukocytes are the reservoir of CMV in these asymptomatic blood donors, prevention of transfusion-transmitted CMV has been attempted using leukocyte-reduced components.

Two small studies [93,94], one large controlled trial [91], and a meta-analysis [8] have established that leukocyte-reduced components are as effective as antibody-negative components in preventing transfusion-transmitted CMV. With both CMV antibody-negative and leukocyte-reduced blood, there is a small residual risk of CMV transmission of about 2–3% [95,177], which could be due to plasma viremia in seroconverting donors [96]. In the large study [91], there was no difference in the CMV seroconversion rate between patients who received leukocyte-reduced components and those who received CMV antibody-negative components. However, the few cases of clinical CMV infection occurred in the leukocyte-reduced group, compared with only seroconversion in the CMV antibody-negative group. This has caused some transplant physicians to prefer CMV antibody-negative blood components when they can be obtained. In most centers, leukocyte-reduced and antibody-negative components are considered equivalent and used interchangeably depending on the logistical considerations of each transfusion service [97].

The use of CMV antibody-negative blood components in potential HCT patients who are CMV antibody negative has been suggested. This would prevent these patients from becoming infected with CMV as a result of transfusions received earlier in their disease and before entering an HCT program. This practice is gaining in popularity, and the conversion to routine use of leukocyte-reduced blood components makes it more practical.

Other approaches that have been attempted for the prevention of CMV infection include the use of CMV intravenous immunoglobulin or ordinary intravenous immunoglobulin, although the increasing use of leukocyte-reduced blood products has obviated these other strategies.

Prevention of transfusion-associated GVHD

GVHD from blood transfusion was originally identified in immunodeficient children. It is now clear that GVHD can occur in a wide variety of immunocompromised and even some immunocompetent patients, but the more common situation in which GVHD occurs is HCT. Following HCT, GVHD is caused by the immunocompetent marrow donor cells, but viable lymphocytes contained in blood components can cause transfusion-associated GVHD in susceptible patients.

Irradiation of blood components

Warning: Hematopoietic stem cells are sensitive to irradiation. Marrow, peripheral blood, or cord blood stem cells that are intended for transplantation should *never* be exposed to irradiation.

To prevent transfusion-associated GVHD, blood components are subjected to irradiation, which interferes with the ability of lymphocytes to proliferate. Gamma irradiation or X-rays damage the lymphocytes by forming electrically charged particles or ions that alter DNA, making lymphocytes unable to proliferate [98]. UV irradiation is not an effective method of damaging lymphocytes to prevent GVHD unless it is combined with other agents as in pathogen inactivation technology (see later). Blood banks that provide large numbers of irradiated products usually irradiate with a dedicated instrument. These instruments use caesium-137 or cobalt-60 as the source of the radioactivity. Recently, relatively simple X-ray devices have been produced for use in the blood bank.

Gamma irradiation at a dose of only 500 cGy will abolish lymphocyte proliferation in mixed lymphocyte culture [99], and doses up to 5000 cGy reduce the incorporation of [^{14}C]thymidine into mitogen-stimulated lymphocytes by 85.0–98.5% [100]. Red cell survival in vivo and in certain in vitro assays are normal after up to 10,000 cGy [101]. Granulocyte chemotaxis may be slightly reduced by even 500 cGy, but this defect does not become significant until above 10,000 cGy [100]. Very high doses such as 40,000 cGy are required to interfere with phagocytosis and microbial killing. In vitro platelet function studies have generally been normal following up to a 5000 cGy dose [99]. Studies involving lower doses of irradiation such as 2500 or 3000 cGy have shown normal platelet in vivo survival [102] and post-transfusion increments [103]. hence it appears that doses of irradiation up to 5000 cGy do not have an adverse effect on red cells, platelets, or granulocytes.

One difficulty in selecting an irradiation dose is the lack of a definitive in vitro assay to establish a clinically effective dose, because of the occurrence of transfusion-associated GVHD in several individuals who received blood components supposedly irradiated with at least 1500 cGy [104–106]. The limiting dilution assay has been proposed as a good indicator of the effects of irradiation on lymphocytes because this assay detects a 5 $\log_{10}$ reduction in viable T cells, compared with a 1–2 $\log_{10}$ reduction in the mixed lymphocyte culture [98]. Studies using the limiting dilution assay showed that 2500 cGy completely eliminated T-lymphocyte growth, and, based on this experience, the FDA has recommended a minimum dose of 2500 cGy. Important practical factors are the configuration of the blood containers in the irradiated field, the distribution of irradiation within the field, and quality control methods to assure that the desired dose is actually being administered [98].

Storage of irradiated components

As the use of irradiated blood components has increased, interest has developed in irradiating the components after collection and storing them for use days or weeks later. Doses of 2000 or 3000 cGy to units of red cells result in potassium levels that are two and three times normal, respectively, after storage for 4–5 days [107]. This leakage suggests damage to the red cell membrane or the sodium–potassium pump. Some blood banks wash red cells that have been stored for several days after irradiation. However, in a thorough review, Strauss concluded that washing is not necessary for most clinical situations [108]. Based on these studies, red cells can be stored for only 28 days after irradiation. Because there is no reduction in platelet recovery and survival when previously irradiated platelets are stored [102], platelets can be irradiated and stored for the usual 5 days.

Leukocyte reduction to prevent GVHD

Because blood filters are very effective in removing leukocytes, the question has arisen as to whether blood filtration might be an alternative to irradiation for prevention of GVHD. Although, on average, filters produce components that contain fewer than 5×10^6 leukocytes, a small proportion of units may contain considerably more leukocytes. Thus, filtration is not an acceptable approach to prevention of transfusion-associated GVHD.

Pathogen inactivation and prevention of GVHD

Pathogen inactivation technologies damage nucleic acids and thus prevent cell (and also microbial and lymphocyte) multiplication. Hence blood components subjected to pathogen inactivation do not cause GVHD [109–111]. Many centers using pathogen inactivation to treat platelets no longer use irradiation [112].

Irradiation of blood products for autologous bone marrow transplantation

Although there may be some differences in the preparative regimen for autologous compared with allogeneic HCT, patients undergoing autologous bone marrow transplantation are severely immunocompromised for several weeks. The use of irradiated blood components has been adopted for autologous HCT without clinical or laboratory study.

Non-cellular blood components

Transfusion-associated GVHD has occurred in patients with congenital immune deficiency following transfusion of fresh liquid plasma [104,113,114] but has not been reported to be caused by previously frozen components such as FFP or cryoprecipitate. Plasma components contain fragments of leukocytes but few, if any, viable lymphocytes. They would not be expected to cause transfusion-associated GVHD. Although irradiation of FFP and cryoprecipitate is probably not necessary, many blood banks do irradiate these components to avoid clerical errors in which a cellular blood component might not be irradiated when necessary.

Transfusion therapy for HCT donors

Patients (autologous donors) or normal allogeneic donors of marrow may require some replacement of red cells. The volume of replacement needed can be predicted from the size of the patient and the donor [115]. It is important to anticipate whether red cell transfusion of the normal allogeneic donor will be necessary and, if so, to take steps to avoid exposure to allogeneic red cells. If red cell replacement is contemplated, the normal donor should provide autologous red cells for transfusion during marrow donation [115]. Usually, two units of red cells suffice. Erythropoietin has been used to increase erythropoiesis in autologous blood donors before elective surgery, and this step may be a helpful strategy for allogeneic marrow donors, although there are no definitive data on this point.

Various strategies using chemotherapy and/or hematopoietic growth factors are being used to mobilize blood hematopoietic cells for transplantation from either patients or normal allogeneic donors. Leukapheresis is then used to obtain an adequate dose of peripheral blood stem cells for transplantation. Donation of autologous peripheral blood hematopoietic cells by apheresis (see Chapters 36, 37, and 40) involves much less red cell loss than marrow donation, and red cell replacement is usually not necessary. Red cell transfusion may be necessary for autologous donors if the patient is anemic from the disease. Those patients/donors should receive leukocyte-reduced red cells, and the indications for transfusion are those described earlier in this chapter.

Complications of blood transfusion

The complications of transfusion can be categorized as immunologic and non-immunologic. Approximately 1–3% of transfusions result in an adverse effect during or shortly after the transfusion. These effects are considered serious in only about 0.5% of transfusions [116]. The fatality rate immediately surrounding transfusion is estimated to be about 1 per 500,000 patients transfused, or about 35 deaths annually in the United States [117]. The incidence of longer term adverse effects is difficult to establish.

Hemolytic transfusion reactions

Hemolysis can occur as a result of HCT that is incompatible for ABO or other red cell antigens (see Chapter 78). Although these create complex transfusion situations, they are not typical transfusion complications and will not be considered here. Most hemolytic transfusion reactions are due to ABO incompatibility, and a major cause of transfusion fatalities reported to the FDA is ABO-incompatible transfusion. It is estimated that a hemolytic transfusion reaction occurs following about 1 in 150,000 units of red cells transfused [118]. About half of these are of no clinical consequence, but 3–19 patients die from hemolytic transfusion reactions annually in the United States, giving a fatality rate of about 1 per 300,000 patients [17,117]. Other causes of red cell hemolysis in transfusion recipients, such as improper storage or techniques of administering the blood, are not immunologic.

ABO-incompatible hemolytic transfusion reactions are very dangerous because the patient has preformed ABO antibodies that often are immunoglobulin M (IgM) and bind complement, causing activation of the complement system with associated systemic manifestations and leading to red cell lysis. In addition, cytokines cause important biologic effects in hemolytic transfusion reactions. There is substantial production of interleukin-1 (IL-1), IL-6, IL-8, monocyte chemoattractant protein-1, and tumor necrosis factor in response to red cell incompatibility [118], and these act like a final common pathway for both the IgM and IgG red cell-incompatible systems.

The nature and severity of the symptoms do not correlate with the severity or ultimate outcome of a hemolytic transfusion reaction. Some patients may experience a severe reaction after only 20 mL of ABO-incompatible red cells, whereas others may tolerate an entire unit without signs or symptoms. The reaction may begin almost immediately upon beginning the transfusion or up to several hours after transfusion. The signs and symptoms that may accompany a hemolytic transfusion reaction are due to complement activation and release of cytokines, and include fever, chills, flushing, low back pain, hypotension, dyspnea, abdominal pain, vomiting, diarrhea, tachycardia, chest pain, or unexpected bleeding. In addition to the well-known complication of renal failure, a hemolytic transfusion reaction can lead to coagulopathy due to activation of the coagulation system and release of cytokines. Non-ABO antibodies can also cause a hemolytic transfusion reaction, but usually these antibodies are IgG immunoglobulins and cause extravascular rather the intravascular hemolysis. Extravascular hemolysis is usually a slower process with red cells removed by phagocytes and little or no complement activation. Usually, there are few, if any, symptoms.

A delayed hemolytic transfusion reaction can occur in a patient in whom no red cell antibody was detected at the time of compatibility testing but who experiences accelerated destruction of the transfused red cells after an interval during which reactivation of a previous immune response to the transfused red cells occurs. The interval after transfusion may be as little as 24 hours or up to about 1 week. A delayed hemolytic transfusion reaction may be symptomatic or asymptomatic. The most common sign is a decrease in hemoglobin after transfusion, and is the way in which most delayed hemolytic transfusion reactions are identified. Such a reaction can appear as unexplained blood loss following transfusion. In this situation, repeat red cell antibody detection testing should be done, which will usually reveal a red cell antibody that was not present before transfusion.

Febrile non-hemolytic transfusion reactions

These reactions occur in association with about 0.5–1.0% of red cell transfusions and may be common after platelet transfusions [119]. Traditionally, it was believed that they are due to leukocyte antibodies present in the patients that react with leukocytes present in the transfused components. The severity of the reaction is directly related to the number of leukocytes in the blood component. Some febrile leukocyte reactions can be prevented by removing leukocytes from the blood components; however, reactions can still occur, probably because cytokines play a major role (see the later discussion of reactions to transfused platelets). In red cell transfusions, the relative contribution of leukocyte antibody–antigen reactions versus cytokines released from contaminating leukocytes during storage is not known. Both mechanisms are probably important, and both can be prevented by leukocyte reduction of the red cells shortly after they are collected. Previously, the use of leukocyte-reduced blood components was not recommended routinely after a first febrile non-hemolytic transfusion reaction because there is only a small likelihood that a patient will experience a subsequent reaction. As the use of leukocyte-reduced red cells and platelets has become common for HCT patients, the issue of when to convert to leukocyte-reduced blood has become moot. The increased use of leukocyte-reduced blood should decrease febrile non-hemolytic transfusion reactions, and this has been documented with the use of leukocyte-reduced platelets [119].

Patients are often premedicated with antipyretics and antihistamines to prevent or modify febrile non-hemolytic transfusion reactions. Antipyretics do seem to be effective in modifying the febrile response to pyrogens, but premedication is often not effective in preventing chills and fever from platelet transfusions. There is no evidence that antihistamine modifies febrile non-hemolytic transfusion reactions in platelet recipients [120]. Therefore, although antipyretics and antihistamines can be used, expectations should be modest [17,121], and the major benefit is probably from the antipyretic [122].

Allergic and anaphylactic reactions

Allergic reactions are thought to be due to proteins in donor plasma to which the recipient was previously sensitized. Recipient mast cells and basophils containing IgE antibody become activated and release complement components, cytokines, or other vasoactive substances that cause the reaction. Reactions due to this mechanism may range from mild, involving only hives, to severe anaphylaxis with laryngospasm and shock. Allergic reactions that involve only hives with no other symptoms are probably the most frequent kind of reaction, occurring after 1–2% of transfusions. These reactions are the only situation in which the transfusion is stopped and the patient can be given an antihistamine and the transfusion can be restarted after 15–30 minutes.

Patients who are IgA deficient and have anti-IgA antibodies may experience an anaphylactic reaction if they receive blood components that contain IgA [123]. The treatment is the same as for any anaphylactic reaction. The reactions can be prevented by using red cells or platelet concentrates, washed to remove plasma IgA, and using plasma components prepared from IgA-deficient donors. Although it is a complex process, IgA-deficient patients can be managed successfully while undergoing HCT [124].

Pulmonary reactions: transfusion-related acute lung injury

Following transfusion, a very severe type of transfusion reaction is the acute, sometimes fatal, pulmonary reaction that has been termed transfusion-related acute lung injury (TRALI). TRALI is a clinical syndrome, not a single disease. It is defined as new acute lung injury occurring within 6 hours of transfusion and including hypoxemia and chest X-ray indicative of alveolar or interstitial disease but without circulatory overload [125].

Patients develop acute respiratory distress, hypoxemia, diffuse pulmonary infiltrates on X-ray, and the general clinical presentation of non-cardiogenic pulmonary edema. Fever and hypotension may also occur, and symptoms begin less than 6 hours after the transfusion is initiated. Because it is a clinical diagnosis, the incidence is difficult to determine but may be about 1 per 4500 units of blood depending on the specific component [125]. Two hypotheses for the etiology of TRALI seem to be merging. Leukocyte (HLA or granulocyte-specific) antibodies in donor plasma are one inciting cause of TRALI, being found in almost 90% of cases. An alternative hypothesis is a two-stage process in which platelet-activating factor or cytokines or bioactive lipids that accumulate in blood during storage cause general activation of neutrophils. Then a second insult such as a leukocyte antibody–antigen reaction leads to pulmonary endothelial adherence and damage. It has been suggested that TRALI is more common than currently believed and that, to avoid it, plasma from multiparous donors should not be used because of their likelihood of having HLA antibodies. Most blood centers now produces plasma products for transfusion from mostly male donors [126]. Apheresis platelets are still produced from both male and female donors because of limitations in donor availability. Screening of donors for HLA or granulocyte antibodies is not an effective strategy for TRALI prevention. The prompt recognition that pulmonary symptoms occurring during or shortly after transfusion could be due to TRALI allows prompt initiation of respiratory supportive therapy. This intervention is important because TRALI is a transient phenomenon that clears usually within 72 hours.

Reactions to platelet transfusions

Patients with platelet or HLA antibodies may have febrile non-hemolytic reactions, probably due to leukocytes contained in the platelet concentrates. The reactions usually involve chills and fever, but platelets may be trapped in the pulmonary capillaries, causing dyspnea and pulmonary edema. These febrile non-hemolytic reactions occur following 5–30% of platelet transfusions [127]. The reactions have been thought to be due to antibodies to leukocytes and have been considered similar to febrile non-hemolytic reactions from units of red cells. Because these reactions sometimes occur in non-transfused males, are more common when stored platelets are used, and are more related to the plasma than the platelets in the platelet concentrates, it has become clear that bioactive substance other than leukocyte antibodies are involved [127].

Leukocytes in the platelet concentrates produce cytokines during storage, and platelet transfusion reactions are correlated with the concentration of IL-1 and IL-6 in the plasma [128,129]. A landmark study [127] established that many (if not most) reactions to platelet transfusion are due to cytokines, not antigen–antibody reactions. Removal of the leukocytes soon after collection of the blood prevents the accumulation of cytokines in the platelet concentrate and avoids platelet transfusion reactions [76,128,130]. Removal of leukocytes by bedside filtration at the time of transfusion does not decrease the incidence of platelet transfusion reactions [130] because cytokines will have accumulated from contaminating leukocytes during storage. Therefore, platelet concentrates should be depleted of leukocytes either as part of the apheresis collection procedure or by filtration at the time of production and not later, at the time of transfusion.

Allergic reactions can also occur with platelet transfusions. Most allergic reactions are thought to be due to proteins in the donor plasma. New electrolyte-based platelet storage solutions replace most of the donor plasma and may lead to a major decrease in allergic reactions [131].

Reactions to granulocyte transfusions

Transfusion reactions are common following granulocyte transfusions. Many of these reactions are probably due to the physiologic activity of the large dose of granulocytes being administered to infected neutropenic patients, or to cytokines contained in the granulocyte concentrate. Since granulocyte concentrates do not undergo a leukocyte cross-match, leukocyte incompatibility may be present in many granulocyte transfusions and may also account for some reactions. At one time, it was believed that granulocytes transfused in association with amphotericin infusion resulted in severe pulmonary reactions with sequestration of granulocytes in the lungs. Subsequent experience has not supported this. With the large number of intravenous medications that these patients receive and the importance of transfusing granulocytes as soon as possible, it is often not practical to space the granulocyte transfusion several hours apart from amphotericin or other similar infusions. Hence a gap of several hours between amphotericin and granulocytes is suggested but is not absolutely necessary.

Other immunologic complications of transfusion

As a result of exposure to blood, patients may form antibodies to red cells, to lymphocyte, granulocyte, or platelet surface antigens, or to plasma proteins. The likelihood of antibody formation depends on the immunogenicity of the antigen and the ability of the individual to mount an antibody response. Each kind of antibody can cause a particular clinical problem later if the patient requires subsequent transfusions or organ or tissue grafts, or becomes pregnant. The first observation of transfusion-related immune modulation was the beneficial effect of transfusion on renal graft survival. In the last decade, considerable debate has developed over whether transfusion also leads to increased cancer recurrence and/or postoperative infection [6–8]. Although there is general agreement that transfusion has an immunomodulating effect, the clinical impact of this effect is not established.

Bacterial contamination of units

Bacterial contamination continues to be an important complication of blood transfusion [17,132]. The two general types of problem are bacterial contamination of platelet concentrates stored at room temperature and transmission of bacteria, especially *Yersinia enterocolitica*, from red cells stored at refrigerator temperatures [133]. Bacterial contamination probably occurs most commonly from skin flora at the venepuncture site. Other less likely possibilities are contaminated bags or solutions, contamination of ports during water-bath thawing of frozen products or during platelet pooling, or asymptomatic bacteremia in the donor. The extent of the problem is difficult to ascertain, but a positive bacterial culture has been reported in 0.3–0.4% of units of red cells and platelets [134,135], although most of these units do not cause a clinical problem. Blood banks now culture platelet units. Rates of bacterial contamination of platelets as high as 230 per 100,000 platelet units and 3 per 100,000 red cell units have been reported [17]. Clinically important transfusion-transmitted bacterial infections probably occur about 1 per 25,000 units of platelets and 1 per 250,000 units of red cells [17,136–138]. Up to eight fatalities have been reported to the FDA (Ref. 17, Chapter 14, US Department of Health and Human Services). A method is available for testing for contamination at the time of release of the platelet unit from the blood bank, but this is not yet widely used. The signs and symptoms of transfusion of contaminated platelets are variable and include chills and fever, usually beginning during the transfusion, possibly followed by nausea, vomiting, hypotension, oliguria, and respiratory symptoms. Although the problem of contaminated blood products, especially platelets, has been reduced, this potential serious adverse effect has not been eliminated. Because of the reduction in transmission of viral diseases that has occurred in the last two decades, bacterial contamination of blood components is now potentially the most serious complication of transfusion, especially in the immunocompromised recipient.

Non-immunologic complications of blood transfusion

Non-immunologic complications of transfusion include hypothermia from transfusion of large volumes of red cells that have been stored in the refrigerator, citrate toxicity that may manifest itself as hypocalcemia, and a bleeding tendency since red cells suspended in the additive preservative solution do not provide coagulation factor replacement. Proper management of fluid balance can avoid circulatory overload. Iron overload is a complication of patients who receive many transfusions, such as patients with hemoglobinopathies. It is a problem in HCT for patients with thalassemia major and may require an iron removal program following HCT (see Chapter 71) [139,140] . Air or particulate emboli that were a problem in the early days of transfusion no longer occur if proper techniques are used to administer the blood.

Transfusion-transmitted diseases

The acquired immune deficiency syndrome (AIDS) epidemic greatly increased the fear of transfusion-transmitted diseases. The risks of transfusion can be reduced by donor selection, transmissible disease testing, limiting the number of donor exposures, and reducing blood use (Table 79.3). Physicians have become much more conservative in the use of blood by changing the indications for transfusion and by using pharmacologic substitutes. Use of autologous blood became fairly popular but has decreased greatly owing to the safety of the general blood supply and more conservative use of blood. Directed donor programs in which relatives or friends donate for a specific patient are discouraged because they provide no safety advantage and are complex and costly. Donor eligibility criteria reflect the understanding of behavior that places potential donors at risk of transmitting disease. The number of donor screening questions is large and the nature of the questions is quite specific. These strategies have been remarkably successful. For instance, changes in donor selection resulted in a 90% decrease in the human immunodeficiency virus (HIV) infectivity of the blood supply in the San Francisco Bay area even before the introduction of the anti-HIV test [141]. Currently, a complex process is used to obtain the safest possible donors.

Laboratory testing of donated blood has also greatly expanded (Table 79.4). This is extremely effective in reducing the risks of blood transfusion. Original screening tests for HIV and hepatitis C virus (HCV) detected antibodies to these viruses and, thus, there was a "window phase" between exposure to the virus and the development of a positive screening test. During this window phase, the blood can be infectious. Nucleic acid amplification tests are now used to detect the infectious agent rather than antibodies to the agent [142–144]. All blood collected in the United States and most developed countries is currently being screened for HIV, HCV, and West Nile virus using nucleic acid amplification, and testing for hepatitis B virus (HBV) has been added. This testing strategy has virtually eliminated the window phase of blood donor infectivity. Estimates of disease transmission [145,146] are given in Table 79.5. A brief review of transfusion-transmitted diseases is presented below.

Table 79.3 Strategies to reduce transfusion-transmitted disease

- Careful donor selection
- Careful transmissible disease testing
- Limit donor exposure
- Minimize blood use
  - Changed indications for transfusion
  - Pharmacologic stimulation or substitution
- Modification of the blood component
- Viral and bacterial inactivation

Syphilis

Transmission of syphilis by blood transfusion was common in the early days of blood transfusion but now it is extremely rare, the last case in the United States being reported in 1966 [147]. Syphilis testing is still required of all donated blood despite the fact that the test is almost always negative when circulating spirochetes are present. Syphilis testing today probably does not contribute to blood safety, although the FDA has not agreed to calls for elimination of syphilis testing [148,149].

Hepatitis

Post-transfusion hepatitis is the most common disease transmitted by blood transfusion and is a major public health problem. It can be caused by hepatitis A, B, C, and E viruses, CMV, Epstein–Barr virus (EBV), and possibly other viruses. Prospective studies in the 1970s showed rates of post-transfusion hepatitis as high as 35%, but that was substantially reduced in the United States and other countries due to the conversion from paid donors to volunteer donors and improved testing [150].

Hepatitis A usually has a short period of viremia, symptoms occur early during the viremic phase, and there is no carrier state. Because there is no chronic viremia and symptoms coincide with the acute viremic phase, infectious donors are usually identified by the medical history. Hence post-transfusion hepatitis A is rare [151,152]. Laboratory testing of blood donors for hepatitis A is not done. Hepatitis A can be transmitted by coagulation factor concentrates or rarely by plasma derivatives. In evaluating a patient with suspected post-transfusion hepatitis, hepatitis A should be considered, but only as a remote possibility.

Most people infected with the HBV virus are asymptomatic, hence an apparently healthy individual may meet all of the donor medical history criteria and donate a unit of infectious blood. Blood is screened for HBV by testing for hepatitis B surface antigen and more recently by nucleic acid amplification [145,146,153]. A recent estimated positive rate is 1 per 450,000 donations [153]. This is a remarkable improvement in blood safety from the 35% incidence of post-transfusion hepatitis in the 1970s [150].

Acute hepatitis C is usually mild, with up to 80% of patients being asymptomatic. However, the long-term effects are more serious because the virus tends to be persistent and the condition develops into chronic liver disease [154–156]. All blood is screened for HCV using nucleic acid amplification technology. It has been estimated that the introduction of hepatitis C testing of blood donors has prevented about 40,000 cases of post-transfusion hepatitis C annually in the United States [156]. With the introduction of

Table 79.4 Laboratory testing for transfusion-transmitted diseases

Family	Pathogen	Disease	Routinely screened for in the USA	
			Yes	No
Hepatitis	HBV, HCV	Hepatitis	X	
	HEV, HGV	Hepatitis		X
Retroviruses	Human immunodeficiency virus-1 and -2	Acquired immune deficiency syndrome	X	
	Human T-lymphotrophic virus-I and -II	Malignantly lymphoproliferative disorders, neuropathy	X	
Herpesviruses	Cytomegalovirus	Cytomegalovirus retinitis, hepatitis, pneumonia	X	
	Epstein–Barr virus	Epstein–Barr syndrome		X
	Human herpesvirus-8	Kaposi's sarcoma		X
Flavivirus	West Nile	Meningitis, encephalitis	X	
	Denge	Hemorrhagic fever		X
Parvoviruses	B19	Aplastic anemia		X
Bacteria	Gram negative, Gram positive	Sepsis	X	
	Treponema pallidum	Syphilis	X	
	Borelia burgdorferi	Lyme disease		X
	Rickettsia rickettsii	Rocky Mountain spotted fever		X
	Ehrlichia chafeensis	Ehrlichiosis		X
Protozoans	*Trypanosoma cruzi*	Chagas disease		X
	Babesia microti	Babesiosis		X
	Leishmania donovani	Leishmaniasis		X
	Plasmodium sp.	Malaria	X	

HBV, HCV, HEV, HGV, hepatitis B, C, E, G viruses, respectively.

Table 79.5 Estimated risk of transfusion-transmitted infections in the United States

	United States	
	Risk donations	Estimated number of cases annually[a]
Human immunodeficiency virus	2,135,000	5.6
Hepatitis C virus	270,000	12.8
Hepatitis B virus	410,000	58.5
Bacteria	75,000	160

[a] Based on 12,000,000 units of whole blood collected annually in the United States.
Source: data from [145,146].

nucleic acid amplification testing, very little transfusion-transmitted hepatitis C remains (Table 79.5).

Despite the discovery of the HCV and implementation of screening donated blood for this virus, a few patients with post-transfusion hepatitis test negative for the known hepatitis viruses. Other hepatitis-related viruses that have been investigated and found not to be related to transfusion-transmitted hepatitis are hepatitis G or GB, TT virus and SEN virus [17,157–159]. Hepatitis E is endemic in some parts of the world and apparently can be transmitted by transfusion [17,160]. It is not established that hepatitis E virus is an important form of transfusion-related hepatitis.

Human immunodeficiency virus

Although HIV-1 infection can be transmitted by blood transfusion, only a very small proportion of AIDS cases are due to transfusion. The risk of acquiring HIV infection following transfusion with anti-HIV-1-positive blood is as high as 70–91% [161]. It has been estimated that, before the introduction of HIV-1 antibody testing in May 1985, approximately 12,000 patients were infected with HIV-1 by transfusion [162].

Because there is the interval or "window" between infection and the development of antibody to the infecting virus, HIV infection can be transmitted by anti-HIV-negative donors if they are in this window period [163–165]. Screening of blood for the HIV antigen using enzyme-linked immunoassay technology to eliminate the window phase was not effective. Nucleic acid amplification testing is now applied to all donated blood and has nearly eliminated transfusion-transmitted HIV (Table 79.5) [144–146].

Human T-lymphotrophic virus I/II

Human T-lymphotrophic virus-I (HTLV-I) is the first retrovirus that has been shown to cause malignancy, adult T-cell leukemia, in humans. The virus is also associated with a form of myelopathy referred to as HTLV-associated myelopathy or tropical spastic paraparesis. Donors with a true positive test for HTLV-I/II have approximately a 1–5% chance of developing adult T-cell leukemia during a 70-year lifespan, and another 2% may develop tropical spastic paraparesis within 5–10 years of initial infection. Although no cases of transfusion-transmitted adult T-cell leukemia or tropical spastic paraparesis have been identified, transmission of the virus by blood transfusion does occur [166]. In the United States, anti-HTLV-I is found almost exclusively in intravenous drug abusers or persons from areas that are endemic for HTLV-I [167]. Because of the potential for disease transmission, although no cases of transfusion-transmitted adult T-cell leukemia have been identified, routine testing of all donated blood for anti-HTLV-I was initiated in the United States in December 1988.

Parvovirus

The parvovirus B19 has been transmitted by blood transfusion (see Chapter 93) [168,169]. The prevalence of parvovirus in blood donors is estimated to be 1 in 3300 to 1 in 50,000 [168,169]. The low prevalence, combined with the brief period of viremia, makes transmission of parvovirus by blood transfusion rare. Transmission also occurs from coagulation factor concentrates [169] and albumin. However, the few cases of transmission by single-donor components suggest that although rare, transfusion-transmitted parvovirus infection could be a particular problem for HCT patients [169–172].

Epstein–Barr virus

Infection with EBV is followed by a lifelong carrier state, and most adults have been infected (see Chapter 90). EBV can be transmitted by transfusion [173], usually as the "postperfusion" syndrome, a virus-like illness that occurs after transfusion of fresh blood during open heart surgery. Transfusion transmission of EBV has not been a major clinical problem in HCT (see Chapter 90), although it can be transmitted to organ recipients [174] and could cause lymphoproliferative syndrome in HCT patients. No strategies are used to avoid transfusion transmission of EBV.

Parasitic diseases

It has been known for many years that some parasites are transmitted by transfusion. All species of *Plasmodium* can survive in refrigerated blood and have caused transfusion-transmitted malaria, although most cases involve *P. malariae.* All components, including RBCs, WBCs, platelet concentrates, and fresh plasma, can transmit malaria [175]. The prevention of transfusion-transmitted malaria relies on the exclusion of asymptomatic carriers based on residence or travel to an endemic area. However, in most cases of post-transfusion malaria, the interview fails to exclude the infectious donors. Laboratory tests are not used in the United States for screening donors for malaria. Thus, periodic spiking fever in a patient who has recently received a transfusion could be due to malaria, but this is very unlikely in North America.

Trypanosoma cruzi is endemic in many parts of Central and South America. Many patients with chronic *T. cruzi* infection may be asymptomatic, and therefore could pass the blood donor medical questions and donate blood. *T. cruzi* survives in refrigerated blood and can be transmitted by transfusion, although this event is rare in the United States [176]. For instance, in screening more than one million donors, none was found to have antibodies to *T. cruzi* from investigation of the recipients, and not a single case of transfusion transmission was found. Despite this, blood banks are now testing all blood donors for *T. cruzi* antibodies one time, but then not on subsequent donations.

Babesia microti and *Babesia bovi* are protozoa that occasionally infect humans by tick bites. Many infected individuals are asymptomatic, and *B. microti* can therefore be transmitted by blood donated by asymptomatic infected donors [178–180]. The ticks are prevalent in the Northeast, Mid-Atlantic, and Upper Midwest. A suitable donor screening test will be available soon and decisions regarding donor screening will need to be made soon in high prevalence areas of the Northeast and Upper Midwest.

Borrelia burgdorferi, the spirochete that causes Lyme disease, is transmitted by ticks to humans. In up to 40% of persons, the infection is asymptomatic, and the spirochetes survive in stored blood for up to 45 days [181]. Hence transmission of *B. burgdorferi* by transfusion is theoretically possible, but this has not been reported. Although a serologic test is available, it is not a suitable laboratory test for donor screening, and the widespread prevalence of the tick makes it impractical to defer donors from endemic areas.

Creutzfeldt–Jakob disease

A variant of Creutzfeldt–Jakob disease (CJD) that appears to be associated with ingestion of beef from cows affected with bovine spongiform encephalopathy or "mad cow disease" [182] raised the question of whether the variant of CJD could be transmitted by blood transfusion. CJD has been transmitted by dura, corneas, and pituitary growth hormone from CJD patients and electroencephalographic electrodes used on CJD patients [183]. Prions, thought to be involved in CJD, are highly resistant to inactivation with methods currently used in the production of plasma derivatives. Thus, even one unit of plasma contaminated with the CJD agent could render a large lot of plasma derivatives infectious, such as occurred with HIV. However, it appears that, during the manufacture of plasma derivatives, prions do not segregate with the plasma fractions that result in coagulation factor concentrates or immune globulins.

There is no evidence of blood-borne transmission or of a recent "outbreak" of CJD in the United States [184]. There have been two reports from the United Kingdom of transfusion recipients who developed CJD after receiving blood from donors who later developed CJD [185,186]. Although this does not definitively establish transmission of variant CJD, the occurrence is statistically highly unlikely, suggesting that transfusion transmission might occur. Tests of the causative agent, presumably a prion, are under development but not available for donor screening. In an effort to decrease the transfusion risk, if one exists, potential blood donors are deferred if they have spent a prolonged time in an area of high incidence of variant CJD such as the United Kingdom and parts of Europe.

West Nile virus

West Nile virus, a mosquito-borne agent, was endemic for years in Uganda and entered the United States in 1999. West Nile virus is a typical viral illness with only a few infected individuals being symptomatic with fever, chills, headache, myalgia, arthralgia, and weakness. However, viremia in asymptomatic individuals makes transfusion transmission possible. As the West Nile virus epidemic became more widespread, transfusion transmission was identified [187–189]. The existing nucleic acid amplification test systems for HIV and HCV provided a platform for introduction of West Nile virus testing, and currently all donated blood in the United States is tested for West Nile virus, at least during epidemic seasons so this risk should be nearly but not entirely eliminated.

Chickungunya and Dengue Fever Virus

These mosquito born infections are now present in the Caribbean and South Florida and may be transmitted by transfusion. No intervention steps are in place other than medical interview.

Summary of transfusion-transmitted diseases

The diseases of most concern for transmission by blood transfusion have been discussed here. However, there is a concern that emerging pathogens, the mobility of people, and continued immigration can alter the situation with transfusion-transmitted diseases. Blood safety depends on many strategies, not just laboratory tests. The donor medical history and the use of volunteer donors are excellent examples. When considering a new screening test, many factors about the infectious agent and the disease must be taken into consideration. Examples are the prevalence of the disease, infectivity of the agent, status of the epidemic, and likelihood of a carrier state. Although some of the diseases may be regional in nature, the mobility of the population may make regional screening practices unsuitable.

However, when all of the scientific discussion is completed, the issues of social policy and the public expectations of its blood supply remain. The public expects the transfusion medicine community to take steps to achieve the maximum possible safety. In the past, policy-makers and politicians have shown little tolerance for failure to take steps that would decrease risks to their constituents regardless of the cost. For instance, the costs of laboratory tests and additional regulations during the past decade have probably increased the cost of blood by 50%, and it has been estimated that introduction of nucleic acid amplification testing for HIV and HCV may have cost as much as $10,000,000 per quality-adjusted life-year saved. A more rational approach to blood safety has been sought by many; however, the decision-making process is still a complex one with no easily discernible structure for these decisions.

Three decades of work and many millions of dollars have not resulted in a safe and effective blood substitute, and it does not appear that one will be available in the near future. In contrast, there has been great progress in the development of techniques to inactivate pathogens in blood products [190–192]. Pathogen-inactivated platelets and plasma are used routinely in many parts of Europe and are recently licensed for use in the United States. Pathogen inactivation also inactivates lymphocytes, thus eliminating the need for irradiation of components [112]. With use of pathogen inactivated blood products, the paradigm for reducing transfusion-transmissible infections will shift from the present reactive to a proactive one involving treatment of blood products to render them non-infectious.

Conclusion

The kinds of blood product available for transfusion have become sophisticated, and transfusion strategies are complex. Beginning with the diagnosis and treatment of the underlying disease, transfusion therapy is designed to minimize its interference with successful engraftment. Following transplantation, patient transfusion needs can be met effectively. The blood supply is safer than ever, and although some risks of infection remain, most patients can be supported safely and effectively.

CHAPTER 80

Vascular Access and Complications

I. Benjamin Paz
City of Hope National Medical Center, Duarte, CA, USA

Introduction

Drs. Thomas Latta and Robert Lewins first attempted the administration of intravenous fluids during the cholera epidemic in England in 1832. After studying the blood and excreta of cholera patients, Dr. William Brooke O'Shaughnessy correctly deduced that the changes in composition of the blood were secondary to the fluid and electrolyte losses in the excreta, and proposed that the treatment of this disease should include the replenishment of fluid and salts intravenously. This was first attempted by Dr. Latta, who administered a hypotonic solution by direct intravenous injection through a silver needle connected to a syringe by rubber tubing; this was reported by Dr. Lewins in *The Lancet* in 1832 [1]. This practice was largely abandoned until the late 1800s, when the administration of intravenous fluids became available thanks to the advent of sterile electrolyte solutions and steel hypodermic needles. In 1945, plastic catheters for continuous vascular access were introduced following the discovery of penicillin and the need for multiple intravenous injections.

The development in the 1960s of long nylon catheters that could be placed into the central veins constituted a major technologic development [2]. These catheters were initially inserted into cancer patients via peripheral vein cutdown and later via percutaneous approaches into the subclavian and jugular veins, with the objective of limiting the chemotherapy-associated phlebitis. A major breakthrough occurred when Broviac et al. described the use of a soft, cuffed, silicone catheter for long-term central venous access in children on total parenteral nutrition [3]. This was shortly followed by the development by Hickman et al. of a similar catheter with a larger lumen for bone marrow transplant recipients [4]. These catheters could remain in place for an extended period of time, facilitating the outpatient care of these patients, and providing higher flow for chemotherapy, blood transfusions, and parenteral nutrition. These devices were further modified by the addition of a subcutaneous reservoir, which could be easily and intermittently accessed via percutaneous needles.

Later, the development of new polymers such as silicone, poly(vinyl chloride), polytetrafluorothylene (Teflon), and polyurethane led to the manufacture of a large variety of intravenous catheters. These catheters had different physical properties designed for specific applications, including chemotherapy, parenteral nutrition, hemodynamic monitoring, and hemodialysis [5,6]. The use of central venous access for treatment and support has improved the quality of life and permitted the delivery of complex chemotherapy regimens to cancer patients. Long-term central venous access has become an essential but risky aspect of the treatment of patients with hematologic malignancies [7]. In the United States, it is estimated that there are at least 250,000 catheter-related bloodstream infections (CRBSIs), resulting in a substantial increase in hospital-related morbidity and cost [8–11]. That led the Centers for Disease Control and Prevention (CDC) to lead a crusade to reduce the frequency of vascular access-related infections [12]. Hence it is imperative that all healthcare personnel understand the indications, selection, and maintenance of catheters, and the prevention, diagnosis, and treatment of catheter-related complications.

Indications and patient selection

Although there are no established guidelines for the placement of central venous access, the use of complex multidrug chemotherapy and bone marrow transplantation in cancer treatment has made the establishment of reliable long-term venous access an essential component of cancer therapy. Important considerations in deciding whether a catheter is indicated are patient preferences, the frequency and duration of therapy, the frequency of blood draws, the nature of the therapy (vesicating agents are better delivered into a central vein without risk of extravasation), the need for support therapies (total parenteral nutrition), the need for hematopoietic cell collection, plasmapheresis, and bone marrow reinfusion.

Long-term venous access is an elective procedure. The patient should be recovered from any acute infections or treatment-related complications that could prevent the safe placement of these catheters. In cases in which patients have not fully recovered and there is an absolute need for central venous access, a temporary percutaneous central line or a peripherally inserted central venous catheter (PICC) can provide access until the patient has recovered. History of prior vascular access insertions (number and location), history of previous CRBSIs, thoracic surgery, radiation, mediastinal, and thoracic disease should alert the surgeon to possible changes in the normal venous drainage. Physical examination documenting the integrity of the skin, normal venous anatomy without evidence of abnormal collaterals, changes secondary to surgical treatment and reconstruction, sites of prior catheter insertions, evidence of venous obstruction, and pulmonary reserve should be completed in every patient.

If there is any evidence of venous obstruction or history of bilateral placements of central venous accesses, the examination should be complemented with a venous imaging study. In patients with a previous history of venous thrombosis, the site can be used for access if the vein is shown to be patent by ultrasound or venogram.

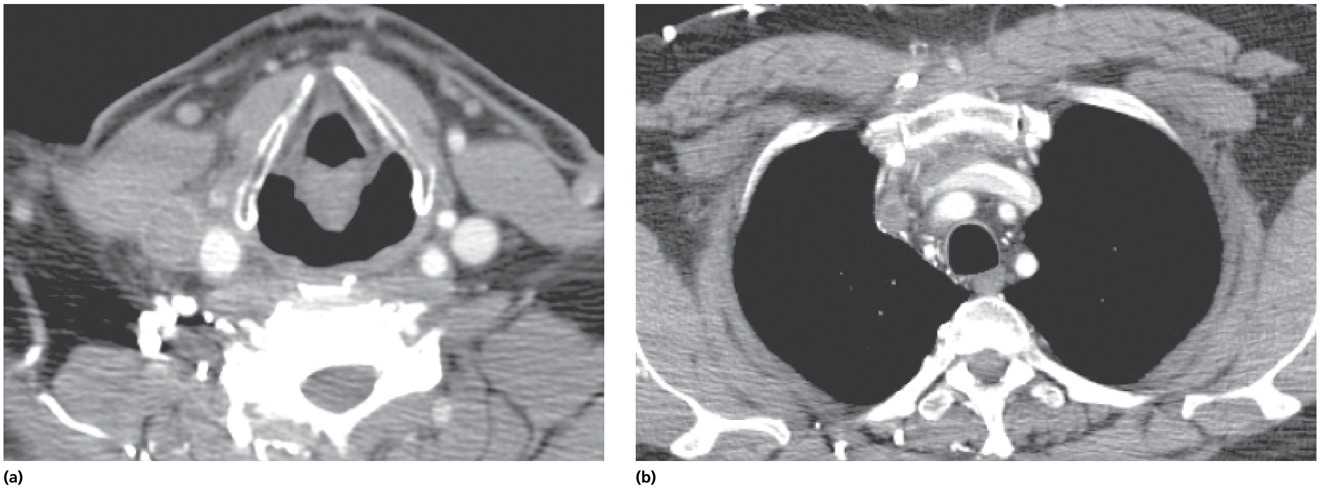

Figure 80.1 (a) Computed tomography (CT) scan showing a right internal jugular vein thrombosis. (b) CT scan showing a superior vena cava thrombosis above the entrance of the innominate vein.

Duplex Doppler ultrasound can visualize the patency and flow of the neck and arm veins. Intrathoracic veins are poorly visualized with this technique. Computed tomography and magnetic resonance imaging are very good at documenting thrombosis and patency of major intrathoracic veins (Figure 80.1). Venous angiogram is still considered the "gold" standard in the study of venous anatomy and should be performed whenever non-invasive examinations fail to provide a definitive diagnosis. Chest radiography can reveal important information such as the presence of pleural effusions, lung metastases, and mediastinal tumors, which can modify the site selection for the placement of central venous access. Table 80.1 provides a list of conditions that should be considered in patient selection.

A relative contraindication to the placement of a permanent central venous access is a granulocyte count less than 1500/mm^3. Such patients have a higher incidence of septic episodes that might prompt early catheter removal. Thrombocytopenia and platelet dysfunction are frequently encountered in cancer patients. Preoperative platelet transfusion to 50,000/mm^3 allows for the safe placement of catheters in the majority of patients without bleeding complications. In those patients with refractory thrombocytopenia to platelet transfusions, venous cutdown might be the safest approach for catheter placement. Many cancer patients have abnormalities in their clotting factors secondary to malnutrition or chemotherapy treatments. Vitamin K or fresh frozen plasma is usually necessary for the correction of these abnormalities. Patients who cannot tolerate the recumbent or Trendelenburg position can frequently have their catheters placed through a cutdown approach under local anesthesia.

Except for those patients who require a line for long-term antibiotic treatment, the only absolute contraindication for the placement of a long-term indwelling catheter is the presence of an active infection.

Table 80.1 Patient and treatment factors that affect catheter selection

Catheter-related factors:
- Duration of therapy (short or long term)
- Frequency of treatment (intermittent or continuous)
- Number of lumina required

Therapy for which the catheter is intended:
- Transfusions of blood products
- Parenteral nutrition
- Chemotherapy administration (types of chemotherapy agent)
- Hematopoietic cell collection
- Supportive care

Patient-related factors:
- Previous history of chest or neck surgery or radiation (mastectomy, neck biopsy)
- Presence of a chest, neck, or mediastinal tumor
- Pulmonary function (asthma, pleural effusion)
- Cardiac function (arrhythmias, pacemakers)

Venous access factors:
- Current venous access
- Previous history of venous access
- Previous history of catheter-related complications
- Previous or current history of veno-occlusive disease or lymphedema

Hematologic and coagulation status:
- Red cell blood count
- Platelet count
- History of bleeding disorders
- Anticoagulation (Coumadin, aspirin, Plavix)

Infection risk:
- White blood cell count
- History of recent infections
- History of catheter-related infections

Allergies:
- Anesthetics
- Cleansing solutions
- Dressings
- Latex

Catheter selection

Long-term venous catheters are designed for external access, such as the Hickman, Broviac, Groshong, and Quinton catheters [13], or for access through a subcutaneous port, such as a Port-a-Cath and Infusaport [14]. These catheters are available with different lumen diameters and as single- and multi-lumina devices [15]. Central venous catheters peripherally placed through an antecubital vein (PICC lines) [16] have become increasingly popular owing to their ease of placement and their ability to be placed by trained nursing personnel. Unfortunately, these devices are associated with a higher incidence of catheter-related complications [9]. In general, treating physicians based on their preferences and the catheter's intended use make the catheter selection. There are very few studies that document patient preferences. In a study of acute leukemic patients randomized to have either dual-lumina subcutaneous ports or dual-lumina cuffed tunneled catheters, patients' perceptions were prospectively documented [17]. Not surprisingly, patients preferred the subcutaneous port, but the study was discontinued owing to a higher incidence of bleeding at the insertion port site.

An important general consideration in the selection of the appropriate catheter is that catheter resistance to infusion depends on the catheter length and diameter of the lumen. During laminar flow, the flow-rate through a catheter is governed by Poiseuille's law:

$$\text{Flow} = \frac{\pi \times (P_1 - P_2) \times R^4}{8 \times n \times L}$$

where P_1 and P_2 are the fluid pressures at the proximal and distal end of the tube, respectively, R is the radius of the tube, n is the viscosity of the fluid, and L is the length of the tube. Flow is then directly proportional to the fourth power of the radius of the tube and inversely proportional to the length [18]. Therefore, variations in the lumen diameter have a greater effect on the flow rate than do changes in the length of the catheter [18]. There is a paucity of recent studies comparing the different catheter materials in the clinical setting. The advantage of a polyurethane catheters is that at equal external diameter, they have a larger inner diameter than silicone catheters. This gives silicone catheters greater strength and bending and break resistance, and gives polyurethane catheters higher flow [6]. From the point of view of thrombogenicity and infection, there does not seem to be a clear advantage of one material over the other [19]. In a randomized study of 228 patients comparing three different subcutaneous ports connected to either silicone or polyurethane catheters, there was a significant higher incidence of catheter breakage with the polyurethane catheters (7.8% vs. 1.3%) [20].

Peripherally inserted central venous catheter (PICC)

The use of PICC lines has become widespread in healthcare since they were first introduced in the late 1970s. Factors that have influenced the popularity of the PICC are its ease of insertion with low complication rate, the ability to be inserted by a trained nurse at the bedside without the need for patient sedation, and the high level of patient satisfaction [21]. As a result, the PICC is the device of choice for patients who require a long-term venous access for antibiotic therapy, parenteral nutrition, pain management, and fluid replacement, but do not require frequent blood samples or infusion of blood products [16]. They are made of either silicone or polyurethane and are available in various sizes, single- or dual-lumina, and can remain in situ for up to 1 year. The use of PICC lines in oncology was initially controversial owing to reported higher CRBSIs and catheter-related venous thrombosis than tunneled or implanted catheters [10,11]. Mollee et al. recently conducted a prospective study involving 1127 lines in 727 patients with hematologic malignancies (54%) and solid tumors (44%) [8]. This study had strict definitions for catheter-associated and related bloodstream infections; the incidence of catheter-associated bloodstream infections (CABSIs) for PICC lines was 4.22 per 1000 days in patients with aggressive hematologic malignancies and 1.1 per 1000 days in patients with other hematologic malignancies. This compared favorably with patients with aggressive hematologic malignancies and tunneled devices who had a CABSI incidence of 7.26 per 1000 days and was essentially the same as the infection rate for patients with implanted subcutaneous ports of 3.89 per 1000 catheter days. In a recent study of 57 patients who underwent autologous bone marrow transplant for hematologic malignancies, the incidence of CRBSI was 1.5 per 1000 PICC days [22]. Recent studies have also documented similar low incidences of PICC-related events in children with hematologic malignancies and solid tumors with an overall incidence of 1.11 complications per 1000 catheter days [23]. The marked decrease in the incidence of CRBSI associated with PICC lines is due to the introduction of rigorous prevention guidelines for catheter-related complications. The use of hand-held Doppler ultrasound increases the insertion success rate, especially in patients with several previous peripheral access insertion attempts. Ultrasound guidance is the preferred method for PICC placement in patients with no clinically identifiable peripheral vein and is an important factor in reducing the trauma associated to the insertion, which has been associated with an increase in PICC-related venous thrombosis (PRVT). Other factors associated with PRVT are the catheter diameter (gauge) and the tip location near the atrial–caval junction. The incidence of PRVT in cancer patients has also decreased and varies widely among studies [21]. Tran et al. reported an incidence of 7.8% symptomatic PRVT among 498 patients with hematologic malignancies; this prompted them to change to a tunneled device placed in the internal jugular vein for the next 667 patients. The incidence of symptomatic venous thrombosis dropped to 0.4% [24]. The retrospective nature of this study did not allow for the control of other known predisposing factors for PRVT limiting the validity of their findings.

Implantable subcutaneous ports

An implantable port is a totally implanted vascular access device that is inserted on the chest wall or in the antecubital area. It is made up of a subcutaneous port containing a silicone septum that is implanted in a subcutaneous pocket, and is connected to a catheter that is inserted in the vein via cutdown or venous puncture using the Seldinger technique. The catheter can be open-ended or have a distal valve (Groshong tip) to prevent blood reflux into the catheter. Randomized studies have failed to show an advantage of the Groshong tip in preventing port-related complications. Furthermore, the inability to draw blood samples increased from 2% for open-ended catheters to 12.5% for the Groshong tip [25]. The port can only be accessed with the use of a non-coring (Huber) point needle, which is inserted through the skin into the septum. The needle can only remain in situ for up to 7 days at a time. The advantage of this port is that it does not interfere with daily activities, does not require local care when it is not accessed, and has a less significant impact on body image. The port requires monthly flushing and is associated with a lower infection risk. Disadvantages of ports include the requirement for a needle for access, the flow rate being limited by the needle diameter, low reliability for obtaining blood draws, higher frequency of catheter occlusion, and the possibility of soft tissue chemotherapy extravasations if the needle is misplaced or migrates out of the port after insertion. Subcutaneous ports are primarily indicated in patients who require intermittent therapy and do not need continuous intravenous access. Subcutaneous ports consistently have the lowest incidence of CRBSI of all the central venous access devices [8,9]. The number of lumina and the flow rate limit its use in patients requiring multiple concomitant intravenous therapies.

Externally tunneled catheter

The Broviac and Hickman catheters were developed in the mid-1970s and constituted the first examples of the skin-tunneled catheter. The tunnel provides a distance between the vein entry site and the skin exit site, and this, along with a Dacron cuff, has been shown to reduce infection risk. The cuff is usually placed about 2 cm from the entry site; the local tissue reaction and granulation tissue entering the cuff prevent infections and catheter dislodgement. These devices provide reliable long-term access and are made of either silicone or polyurethane. Single-, double-, and triple-lumina catheters are available. These devices are usually placed by surgeons, radiologists, or other trained personnel under fluoroscopic guidance via either cutdown or percutaneous venous access. Externally tunneled devices are preferred for those patients who require continuous or frequent catheter access for treatment, blood samples, or support treatment (parenteral nutrition or blood product transfusion) or are receiving potentially toxic therapy if the infusion extravasates into the subcutaneous tissue.

The choice of number and size of lumina should be determined based on the intensity and complexity of the therapy. Pooled studies vary significantly with respect to patient characteristics, catheter maintenance schedules, and diagnosis criteria for infection. Maki and Safdar report an overall mean infection rate of 1.1 per 1,000 catheter days for tunneled catheters and of 0.01 per 1,000 days for subcutaneous ports in a review of over 200 studies [9]. Other important differences between these devices are outlined in Table 80.2.

The hematopoietic cell transplant patient merits special attention. In recent years, the use of peripheral blood progenitor cells has nearly supplanted bone marrow as the preferred autologous hematopoietic progenitor cell source for reconstitution after high-dose chemotherapy. In the past, peripheral blood progenitor cells were collected via a large-bore, stiff, temporary, dual-lumina central venous catheter that provided flow rates of at least 50 mL/min. The apheresis procedure is lengthy and time consuming, since large blood volumes must be processed during multiple sessions until enough progenitor cells have been collected. On the other hand, the transplant process also requires long-term multi-lumina venous access, but only requires a smaller, soft, and flexible catheter for chemotherapy administration, supportive care management (including frequent blood sampling, intravenous antibiotics, analgesics, antiemetics, blood components, and parenteral nutrition), and reinfusion of hematopoietic cells.

Since different catheter properties are required, the transplant procedure traditionally involved the insertion of two venous access devices, one for apheresis and the other for the treatment and supportive care. Over the last few years, the advent of soft silicone and polyurethane catheters specially designed for apheresis treatment has permitted the use of a single catheter for the entire transplant process. These catheters are shorter and have large lumina, staggered at the tip to prevent recirculation during the hematopoietic cell collection [26]. The design of these catheters makes them more likely to kink during placement if special precautions are not taken to maintain adequate flow rates. They also have a very short distance from the cuff to the proximal connectors, which makes them uncomfortable for the frequent venous access required in this patient population. A compromise between these catheters is to place a large-bore (12 Fr.) Hickman catheter with two round lumina of 1.3 mm, each of which provides comfortable access while allowing a 50 mL/min flow rate for a successful apheresis.

Table 80.2 Differences between devices for central venous access

	Peripherally inserted central venous catheter lines	Externally tunneled devices	Subcutaneous ports
Lumen	Single and dual lumina	Single, dual, and triple lumina	Single and dual lumina
Maintenance	Daily; training required	Daily; training required	Monthly; no training required
Activity	Some restrictions	Some restrictions	No restrictions
Blood sample	Low reliability	High reliability	Moderate reliability
Uses	Chemotherapy, TPN, antibiotic therapy, supportive therapy, transfusions	Hematopoietic cell collection and infusion, photopheresis, plasma/red cell exchange, transfusions, supportive therapy, chemotherapy	Chemotherapy, TPN, antibiotic therapy, supportive therapy, transfusions
Cost	Low insertion cost	High maintenance cost	High insertion cost
Access	Painless	Painless	Needle access
Flow	Determined by the lumen	Determined by the lumen	Determined by the needle
Complications	High	High	Low
CRVT	3.4–7.8%	8.6%	0.4–6.1%
CABSI	1.81–7.71 per 1000 catheter-days	1.0–7.26 per 1000 catheter-days	0.1–3.89 per 1000 catheter-days
Placement	Trained nurses; at bedside	Physician, in operating room or radiology	Physician, in operating room or radiology
Removal	Easy	Easy; in the office	Second procedure required

TPN, total parenteral nutrition.

Insertion site selection

The main veins used for central venous access are the internal and external jugular and subclavian veins, which are used for all types of central venous access device. Occasionally, the femoral veins are selected when the above sites are not available or for short-term access. The cephalic and basilic veins are the preferred sites for PICC venous access. The right side of the patient is usually preferred for access from the internal [27] and external jugular vein, and the left side is preferred for access from the subclavian vein [28] because the vessel anatomy allows easier access to the superior vena cava (SVC) and provides the easiest route for the practitioner inserting the device.

Regardless of the insertion site, it is important to pay special attention to the tunneling of the catheter to avoid kinking, and to the location of the tip of the catheter (Figure 80.2). An increased risk of venous thrombosis is associated with the tip of the catheter being located in the upper third of the SVC or in the innominate vein. Even though the lower third appears to be the favored location for the SVC tip, there is still some debate over the optimal location for the SVC tip. A good point of reference under fluoroscopy in the patient in the Trendelenburg position is the carina of the main bronchus bifurcation (Figure 80.3) [29]. Even though right atrial placement is associated with arrhythmias, atrial thrombus, and potential cardiac or valve perforations when the catheter is kept for an extended period of time, it is still performed in some centers.

Several studies have attempted to evaluate the merits of the different venous access sites. Biffi et al. conducted a study in 403 cancer patients who were randomized to have their venous port placed through a percutaneous access in the subclavian or internal jugular vein or by cutdown in the cephalic vein [30]. With 1-year median follow-up, the port-related infection was 0.8, 2.4, and 2.5% for the internal jugular, subclavian, and cephalic vein access, respectively ($p = 0.464$). Likewise, there were no significant differences in the incidence of venous thrombosis. A recent Cochrane Review that included the above-mentioned study failed to show evidence of catheter-related complications (infection, thrombosis, and mechanical complications) for long-term catheters placed in the internal jugular versus the subclavian vein in cancer patients [31]. The same

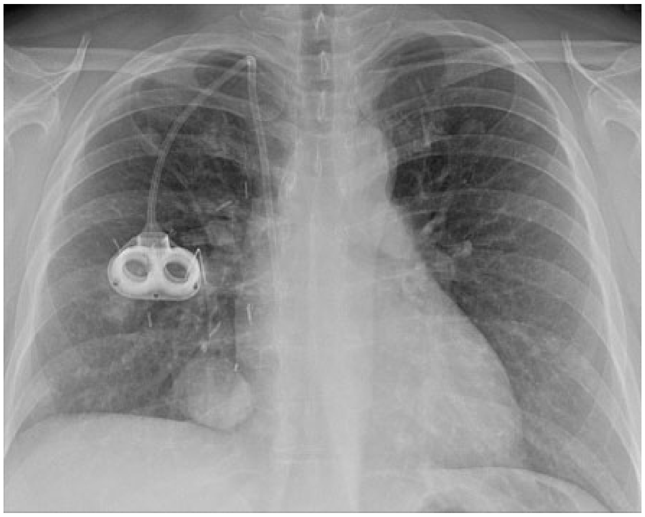

Figure 80.2 X-ray showing kinking of the catheter at the internal jugular vein insertion site.

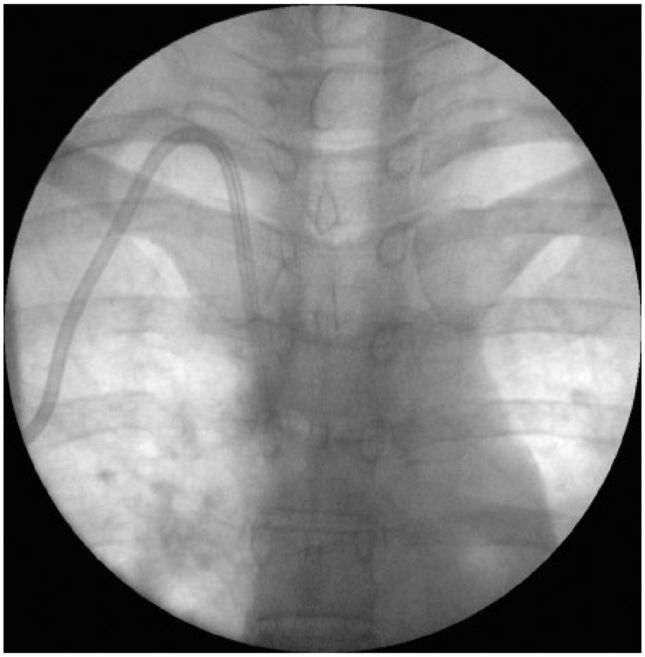

Figure 80.3 Intraoperative fluoroscopy showing the tip of a dual-lumina silicone catheter at the carina. Also note the soft curve at the internal jugular vein entry site.

study showed that for short-term non-tunneled venous access, the femoral vein route had higher colonization (14.2%) rates than the subclavian (2.2%) [relative risk (RR) 6.43; 95% confidence interval (CI) 1.95–21.21] route but not higher CRBSI (1.49% vs. 0.74%). There was also a significant increase in the incidence of catheter-related thrombosis with femoral catheters (21.6%) and with subclavian access (1.9%) (RR 11.53; 95% CI 2.80–47.52).

Insertion technique

Long-term intravenous catheters are better placed in a surgery or radiology suite or a similar outfitted procedure room in order to minimize the incidence of infections. Most procedures are performed on an outpatient basis or immediately prior to chemotherapy admission. Local anesthesia with monitored care and short-acting barbiturates, or conscious sedation with short-acting agents, provides safe and excellent patient sedation [32]. The use of prophylactic antibiotics during the insertion of long-term venous access is controversial; a systematic review of several randomized studies failed to show a significant benefit for this practice [33]. The realization that CRBSI is the leading cause of systemic infection in hematology-oncology patients has led to the development of strict guidelines from the CDC, from the Center of International Blood and Marrow Transplant Research, and from the Bone Marrow Transplant Associations in Amethe United States and Europe [34]. The most important element is the implementation of a CABSI prevention bundle: hand hygiene, full barrier precautions, careful selection of the insertion site to avoid sites with higher infection rates (femoral and internal jugular vein for short-term non-tunneled venous access), use of chlorhexidine for skin preparation, and early removal of unnecessary central venous access [12]. A meta-analysis showed a 50% reduction in catheter-related infections when chlorhexidine gluconate–alcohol-based solutions rather than povidone–iodine solutions were used for entry site care [35].

The use of intraoperative fluoroscopy to document appropriate catheter placement and to prevent complications is highly recommendable. In a prospective study carried out by experienced operators, placement of catheters without fluoroscopic guidance resulted in a 6% incidence of catheter misplacement that required repositioning under fluoroscopy at a later time [36]. The most common technique used in catheter placement is the percutaneous method of Seldinger, which uses the subclavian or internal jugular vein [37,38]. Special care should be taken during the introduction of the wire [39]. In most cases, the guidewire should not be introduced without fluoroscopic guidance for more than 18 cm, which is the average distance in adults from most puncture sites to the atrial–caval junction in adults. Alternatively, a cutdown over the cephalic, external, or internal jugular vein can provide venous access.

For the percutaneous approach, the patient is placed supine, in the Trendelenburg position. The anterior chest, neck, and shoulders are prepared in a sterile manner. The site for venous access is infiltrated with anesthetic, and the right side is most commonly preferred for the internal jugular vein and the left side for the subclavian vein [27,28,40]. The use of ultrasound can aid the placement of the needle, especially when an internal jugular vein approach is attempted [41,42]. The consistent use of ultrasound guidance has decreased the incidence of immediate and long-term catheter-related complications[43]. A systematic review of 18 randomized trials showed that ultrasound guidance for internal jugular vein cannulation was more effective and less expensive than the landmark method, resulting in a faster catheter placement and a higher rate of success in both children and adults [42]. The needle is advanced bevel up carefully and slowly into the vein, while aspirating with the attached syringe (without Luer-lock). No more than three attempts to puncture any given vein should be tried, and the bilateral percutaneous approach should not be attempted in the same session without the confirmation of absence of complications. Vein penetration is confirmed by easy blood flow into the syringe, the syringe is disconnected, preventing air penetration with the thumb, and a flexible J-guidewire is advanced through the needle for no more than 18 cm for most insertion sites and 16 cm for the right internal jugular vein; fluoroscopy confirms the placement of the wire at the atrial–caval junction. Placement of the catheter without fluoroscopic guidance should be discouraged. Pulsatile flow indicates an arterial puncture. When in doubt, the needle should be connected to a pressure transducer before proceeding. After an arterial puncture, the needle needs to be withdrawn, and local pressure should be applied for 5–10 minutes.

Occasionally, in patients with an existing Port-a-Cath, this can be converted to a tunneled device by wiring the existing catheter. This can usually be accomplished if the previous catheter was placed by venous puncture rather than cutdown. This procedure is contraindicated in patients who might have a catheter-related infection and should include routine culture of the removed catheter [44].

Resistance to the advancement of the wire is usually secondary to either misdirection of the wire into a secondary vein or migration outside the vein. Fluoroscopy confirms the wire position; if the wire is outside the vessel, the needle needs to be removed with the wire to prevent its shearing. If the wire requires to be redirected, the needle should be replaced with a 2.5-inch 16-gauge Angiocath, prior to withdrawing the wire. After the successful placement of the wire, the exit site for the catheter, and also the subcutaneous tunnel between this site and the vein access, are anesthetized, and the puncture site is enlarged to admit the catheter and introducer sheath. Placement of the sutures at the catheter exit and vein access site prior to tunneling the catheter prevents potential needle catheter punctures. The catheter is tunneled, measured, and custom-cut to reach the SVC–right atrium junction (approximately the fourth anterior intercostal space) or the tracheal bifurcation under fluoroscopy. The catheter cuff is placed within 2 cm of the exit site.

The dilator and the peel-away introducer sheath are advanced slowly over the wire under frequent fluoroscopy control, gently withdrawing and advancing the wire to confirm that the dilator and sheath are threading over the wire and not migrating outside the vessel. The dilator and wire are withdrawn, and the catheter is advanced through the introducer to the SVC–right atrium junction. Catheter tip placement within the right atrium is associated with a high incidence of right atrial thrombus and occasional supraventricular arrhythmias [45]. Prior to the removal of the introducer, the catheter position should be confirmed by fluoroscopy. Failure to position the beam perpendicular to the patient will provide a false impression of the catheter position. Difficulties in advancing the catheter through the introducer usually imply that the introducer is bent, in which case the introducer should be peeled away slowly while advancing the catheter. This is a frequent occurrence if the catheter is placed through the costoclavicular ligament. The catheter should never be handled with sharp instruments, and only non-toothed forceps should be used if needed (Figure 80.4). The port placement is similar except for the creation of the subcutaneous pocket. The pocket needs to be placed over a hard surface (chest, arm, thigh or pelvis) and should be easily palpable and large enough to allow a no-tension wound closure. The port is sutured to the muscular fascia to prevent port migration or turning.

When the catheter placement has been completed, the catheter position should be examined with fluoroscopy to rule out any kinking that would prevent normal functioning. Catheter infusion (no resistance) and withdrawal (no turbulence) should be tested in the surgical suite prior to heparinization of the lumina. In the recovery room, a chest X-ray should be obtained to rule out complications (Figure 80.5).

Catheter care

Most of the catheter-related clinical care protocols are the product of the individual centers observations, resulting in significant variability among centers in the guidelines used for catheter care and the management of their related complications. In a study of 23 Belgian and Dutch centers for the treatment of patients with hematologic disease, the authors documented great variability in the catheter care guidelines and catheter-related complications treatment protocols among the centers [46]. These findings underscore the need for the systematic implementation of evidence-based catheter-care guidelines and for the ongoing monitoring and reporting of catheter-related outcomes. The CDC has issued an evidence-based guideline for the prevention of catheter-related infections [47]. This comprehensive guideline covers all aspects of catheter selection, insertion technique, and subsequent care. Adherence to these recommendations is essential to achieve a decrease in the incidence of catheter-related infection. Several studies have demonstrated the importance of establishing a hospital-wide program to implement these guidelines systematically and monitor the incidence of catheter-related infections, obtaining sustained CRBSI reductions in the intensive care unit in excess of 66% [48,49]. Neutropenia poses additional challenges in the prevention of CRBSI. To determine the impact of an infection surveillance and catheter-care intervention program, Chaberny et al. studied 268 patients with hematologic malignancies during their neutropenic phase, with 202 of them undergoing bone marrow transplantation [50]. The study was divided into two phases of 18 months each; during the surveillance period, CABSIs and nosocomial infections were collected during the neutropenic phase according to a standardized protocol. After this period, the CABSI rate was calculated and presented to the healthcare personnel. The clinical staff went through an intensive training course to improve catheter-care infection control measures according to established evidence-based guidelines. This included dressing changes, routine catheter-care guidelines, and the use of chlorhexidine–silver sulfadiazine-impregnated catheters. The investigators achieved a 35.8% reduction in the incidence of CABSI episodes per 1000 neutropenic days, but the overall rate of CABSI remained high with a reduction from 38.4% to 26.2%. By multivariate analysis, other factors that contributed to the high incidence of CABSI were the diagnosis of acute leukemia [odds ratio (OR) 1.92; 95% CI 1.12–3.32] and bone marrow transplantation (OR 2.11; 95% CI 1.10–4.26). The implementation of patient education has also been well documented as an important factor in the reduction of CRBSI. In a randomized study of 82 patients with hematologic malignancies with tunneled central catheters, Møller et al. showed a 50% reduction in catheter-related infections [a CRBSI decrease from 4.22 per 1000 catheter days in the control group to 1.92 per 1000 catheter days in the intervention group ($p < 0.05$)] with a patient education and training program [51]. Furthermore, patients in the interventional group assumed ownership of the catheter care and displayed more independence and self-reliance in interviews focusing on clinical and psychosocial outcomes [52]. The M.D. Anderson Cancer Center has had a patient education program in place since 1970, and reported a steady decline in CRBSI per 1000 catheter days from 0.42 in 2006 to 0.12 in 2010 [53].

There is considerable controversy regarding the best occlusive dressing. A systematic review of all randomized trials failed to show a difference in the incidence of infection between gauze and tape versus transparent polyurethane film dressings on CRBSI, catheter dislodgement, tolerance, and reaction to dressing in hospitalized patients [54]. The guideline calls for the use of sterile gauze or transparent or semitransparent dressing to cover the catheter entry site (Category IA). Topical antibiotic ointments should not be used at the insertion site; dressings should be changed if they become moist, loose, or soiled (Category IB). The catheter should not be submerged in water and the connectors should be protected during showering (Category IB). For tunneled cuffed devices, dressing changes are recommended weekly until the insertion site has healed. It is not clear if a dressing is required after the insertion site has healed and the sutures have been removed. A chlorhexidine-impregnated sponge is currently recommended only for short-term non-tunneled catheters at the insertion site. A 2% chlorhexidine wash is used for daily skin cleansing.

Implanted ports require flushing with heparin solution (2–3 mL, 100 U/mL) every 4 weeks or after each use. During treatment, the non-coring (Huber) needle is replaced every fifth to seventh day. Hickman catheters need to be flushed daily with heparin solution (2–3 mL, 100 U/mL) or after each use, and protective caps need to be replaced biweekly. PICC lines require flushing twice per day and after each use with heparin solution, 3–5 mL per lumen. Several studies, especially in children, have documented that the use of vancomycin (25 μg/mL) in the lock solution reduces the incidence of catheter-related infections without increasing the incidence of vancomycin-resistant infections [33,55]. The CDC guidelines recommend the use of prophylactic antimicrobial lock solution in patients with history of recurrent CRBSI in spite of adherence to the rest of guidelines. Studies have shown high levels of catheter patency with the use of non-heparin-containing solutions when a positive-pressure catheter cap is used [56]. Catheters with Groshong tips require weekly flushing with 5 mL of saline solution.

Complications

Complications related to catheter insertion

Complications during catheter placement can be related to the method of insertion or to the experience of the operator. The overall incidence of major complications is approximately 2–5% [57]. The use of imaging during catheter insertion has significantly reduced the incidence of complications, especially during insertion. In a study of 1978 consecutive central venous catheter placements under ultrasound guidance, the vein was accessed on the first attempt in 98.5% of the patients. There was an incidence of arterial puncture of 0.3%, and operators failed to access the vessel in 0.9% of cases [43]. Most importantly, there were no instances of major bleeding, pneumothorax, or nerve puncture. The incidence of complications with the subclavian or internal jugular approach is similar in prospective randomized studies [58]. In general, the incidence of catheter malposition is more frequent with the subclavian approach, and the incidence of arterial puncture is more frequent with internal jugular insertion.

Pneumothorax

This is the most frequent major complication when using the percutaneous technique. A higher incidence of up to 17% is seen in nutritionally compromised and emaciated patients. This complication is also related to the number of attempts to access the vessel and the experience of the operator. Several steps can be taken in order to avoid this complication. The use of a cutdown technique should be encouraged in high-risk patients. Using an ultrasound-guided percutaneous internal jugular vein approach can also effectively avoid this complication. The withdrawal of air during the insertion of the needle is usually secondary to a loose connection between the syringe and the needle rather than a lung puncture.

Pneumothorax can be due to a tear of the pleura or the lung parenchyma. This complication is usually recognized in the postoperative upright expiration chest film, but in some cases is not seen until a few hours or days after insertion. Patients that complain of shortness of breath or pleuritic pain hours or days after the procedure should have a repeat chest X-ray to rule out a delayed pneumothorax or other catheter-related complication. A pneumothorax of less than 30% in an otherwise asymptomatic patient can be observed provided that the pneumothorax does not increase in subsequent films. Symptomatic patients or those with a larger pneumothorax are best treated with a small anterior chest tube thoracostomy connected to a Heimlich (one-way) valve, water seal, or suction [59,60].

Arterial punctures

This frequent and under-reported complication is seen more commonly with the internal jugular than the subclavian vein approach. This complication can be avoided with the use of ultrasound guidance to access the internal jugular vein [61]. The presence of pulsatile flow from the needle confirms the arterial puncture; removal of the needle and compression of the vessel for 5 minutes are usually all that is necessary. If initially missed, the placement of the guidewire to the left of the thoracic spine should be evidence of an arterial puncture (in patients with persistent left vena cava, the wire will also be to the left of the spine; an intraoperative venogram will confirm the diagnosis). If unsure, an Angiocath needs to be placed over the wire and connected to a blood pressure transducer. The introducer sheath should not be inserted until the operator is sure that the guidewire is in the vein.

Hemothorax

This complication, usually due to the perforation of one of the major vessels with the introducer, the needle, or the wire during the catheter placement, is fortunately rarely seen (Figure 80.6) [58,62]. Careful attention to the technique and use of fluoroscopy during advancement of the introducer should prevent this complication. Special attention should be given to the length of the introducer sheath. In the majority of trays, this sheath is 20 cm long; usually no more than 16 cm from the right side and 18 cm from the left side are required to reach the desired catheter tip location. Furthermore, the dilator should only be introduced until the peel-away sheath is in the vein. It can then be withdrawn into the sheath to prevent potential perforations with the tip of the dilator. Most of these patients can be treated with a large lateral tube thoracostomy connected to a closed thoracic suction system. Many of these systems have a blood reinfusion collecting system. Thoracotomy is indicated in patients with persistent bleeding (more than 500 mL/hour) or with massive hemothorax (more than 1500 mL).

Catheter tip malposition

This problem is usually recognized and corrected at the time of surgery with the use of fluoroscopy. Catheters placed in the azygos or internal mammary veins can mimic an SVC placement. These catheters frequently do not withdraw blood easily, and the tip of the catheter does not move with the heart rate; a lateral view of the thorax or a venogram will confirm the position. Placement of the catheter in the proximal vena cava or brachiocephalic trunk usually results in venous thrombosis (Figure 80.7). The ideal tip location is at the atrial–caval junction, with a free-floating tip. Catheter migration after the placement can usually be corrected with an angiographic guidewire placed through the femoral vein.

Catheter occlusion

Placement of the catheter medial and close to the clavicle may cause a compression of the catheter between the clavicle and the first rib. This complication, which may cause fracture and distal embolization of the catheter, can be recognized by the compression of the lumen (pinch-off sign) (Figure 80.8). Selecting a more lateral and lower puncture site can prevent it. If recognized during placement, the catheter should be repositioned through a different venous access site.

Catheter entry site bleeding and hematomas

These complications, which can be prevented with the correction of clotting factors, are frequent in thrombocytopenic patients. Compression over the tunnel and the catheter entry site while the coagulopathy is corrected usually prevents the problem.

Air embolization

This is an infrequently recognized complication during catheter placement that can result in a life-threatening complication. This is especially true in children and patients with spontaneous breathing. The best method to avoid this complication is to ask the patient to do a Valsalva maneuver, or by requesting the anesthesiologist to provide positive ventilation while introducing the guidewire into the needle or the catheter into the peel-away sheath [63].

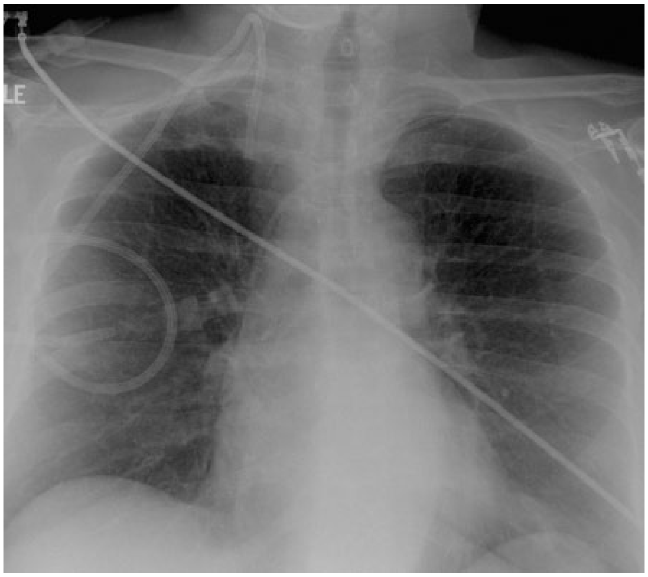

Figure 80.7 X-ray showing right internal jugular vein insertion in the upper third of the superior vena cava. Short catheters usually result in venous thrombosis and catheter dislodgement.

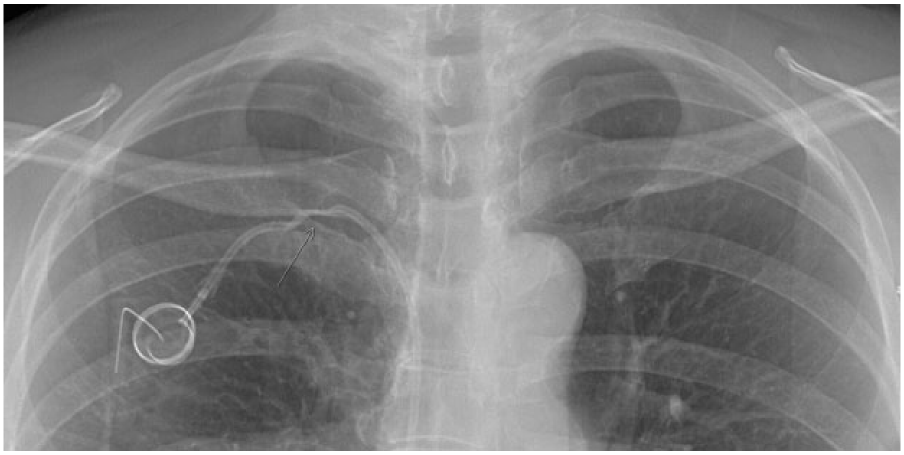

Figure 80.8 X-ray showing subclavian insertion of subcutaneous port with compression of the catheter between the first rib and the clavicle ("pinch-off" sign).

Cardiac tamponade

This insertion complication usually occurs secondary to the guidewire or the dilator. It can be avoided if neither is advanced beyond the atrial–caval junction. The use of fluoroscopy during the procedure helps to prevent this usually fatal complication. This complication, which is sometimes not immediately recognized, can be the result of the migration of the catheter into the pericardium after its placement.

Cardiac arrhythmias

This complication is usually secondary to the wire placement, and some surgeons use the presence of arrhythmias to confirm the placement of the wire into the right atrium. This can usually be avoided if the wire is not advanced beyond 18 cm. Usually; these arrhythmias are limited to a few extra systoles or a short run of supraventricular tachycardia that stops after withdrawing the wire. This complication can also occur after placing the catheter if the tip stimulates the atrial node. This can be avoided by not placing the catheter beyond the atrial–caval junction. Occasionally, this is not recognized until the patient is in recovery or might be diagnosed days after the catheter placement. Patients describe a rapid heart rate usually when they adopt certain positions. To establish the diagnosis, they should be connected to a monitor while they change positions. In rare occasions, a 24-hour Holter monitor is necessary. The presence of a new atrial arrhythmia after surgery usually requires repositioning of the catheter.

Nerve injury

This infrequent complication is due to the needle placement, and is more common with supraclavicular approaches. It can be avoided by using ultrasound during the needle placement. Rarely, it occurs secondary to a hematoma or other local complication. The brachial plexus is the most commonly affected site. Even though the most common symptom is pain, occasionally the patient might also present motor symptoms. Ordinarily, these symptoms are detectable immediately after the procedure. Failure to recognize them immediately is usually due to the effects of the local or general anesthesia. The presence of severe pain that persists days after the procedure, especially if it radiates to the arm or is associated with motor deficits, should be suspicious for a nerve injury. Imaging studies to rule out a hematoma and nerve conduction studies are sometimes needed to confirm the diagnosis. Patients with persistent and out of the ordinary pain days after the procedure sometimes require the removal and repositioning of the catheter in another site. Motor symptoms may require months to recover.

Catheter-related complications

Catheter occlusion or malfunction

Inability to withdraw or infuse through a catheter can be secondary to catheter tip malposition, or kinking, thrombosis of the vein, or catheter occlusion due to clotting or intraluminal precipitation of medications. In a review of 141 cases, Petersen et al. demonstrated that the incidence of catheter malfunction was mainly related to the location of the tip of the catheter in relation to the SVC and right atrium (RA) junction [29]. In this study, catheters located at or below the SVC–RA junction malfunctioned in 2.3% of cases, whereas catheters located above 2 cm from the SVC–RA junction malfunctioned in one-third of cases. In a subsequent series in which they paid attention to the location of the tip of the catheter during placement, they were able to reduce catheter malfunction from 42% to 8%.

Whenever there is problem with infusion or withdrawing from a catheter, 5000 U in 2 mL of urokinase should be injected into the catheter. After 30 minutes, the urokinase should be withdrawn and the catheter tested again. This can be repeated twice and left for longer periods (24 hours) if not effective [64]. Alternatively, 2 mg of recombinant tissue plasminogen activator (TPA) can be used instead of urokinase; the TPA should be left for 30–120 minutes and the dose repeated for a second and third time if catheter patency is not established [65]. This protocol restores catheter flow in 87% of patients [66]. In a double-blind placebo-controlled randomized study that did not required radiographic contrast injection or catheter position confirmation, TPA was shown to be effective in restoring catheter patency in 74% and 90% after the first and second dose, respectively, without reported adverse effects [67]. When compared with regular heparin flushing, the use of prophylactic urokinase failed to prevent these complications [68]. The frequency of catheter occlusions requires the institution of standardized nursing practices in every chemotherapy infusion unit [69].

Inability to withdraw from a catheter might also be due to the development of a fibrin sheath that excludes the catheter from the lumen of the vein [70]. This complication, which occurs in 50–80% of the catheters, does not always result in catheter occlusion. In these patients, a Valsalva maneuver or repositioning of the patient can sometimes allow a successful blood draw. A venogram can usually confirm this etiology (Figure 80.9). These patients rarely respond to a urokinase or TPA bolus. An infusion of 200 U/kg/hour of urokinase, not to exceed 100,000 U/hour, for 6–12 hours is usually more effective. Patients with contraindication for thrombolytic therapy should not be treated with this protocol; fibrinogen levels should be checked and kept above 100 mg/dL. Chemical occlusion can be treated with instillation of a mixture of 0.01 N hydrochloric acid and heparin for calcium–phosphorus precipitation or low-pH medications and sodium bicarbonate for high-pH medications [71]. The solution is irrigated in and out for 2 minutes, clamped for 1 hour, then aspirated. A suggested algorithm for the management of catheter occlusions is outlined in Figure 80.10.

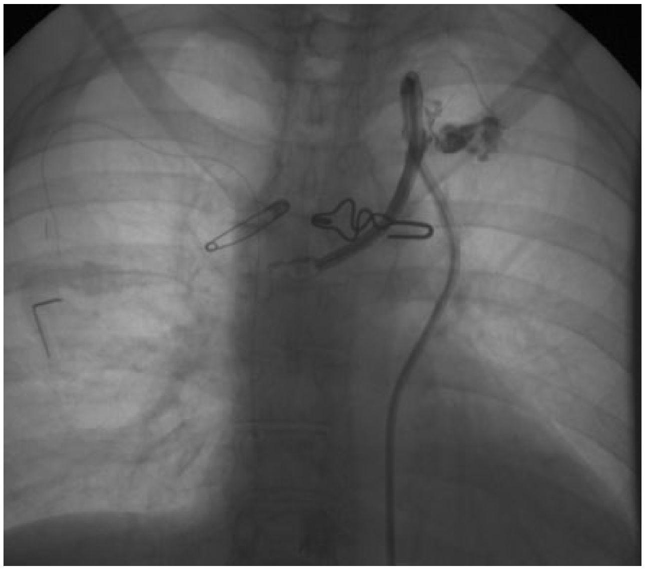

Figure 80.9 X-ray showing catheter tip placed in the innominate vein resulting in venous thrombosis. The injection of contrast through the catheter in this single frame from a video-fluoroscopic study shows no distal flow but contrast reflux around the catheter (fibrin sheath) to small collaterals in the supraclavicular region.

Catheter damage/fracture

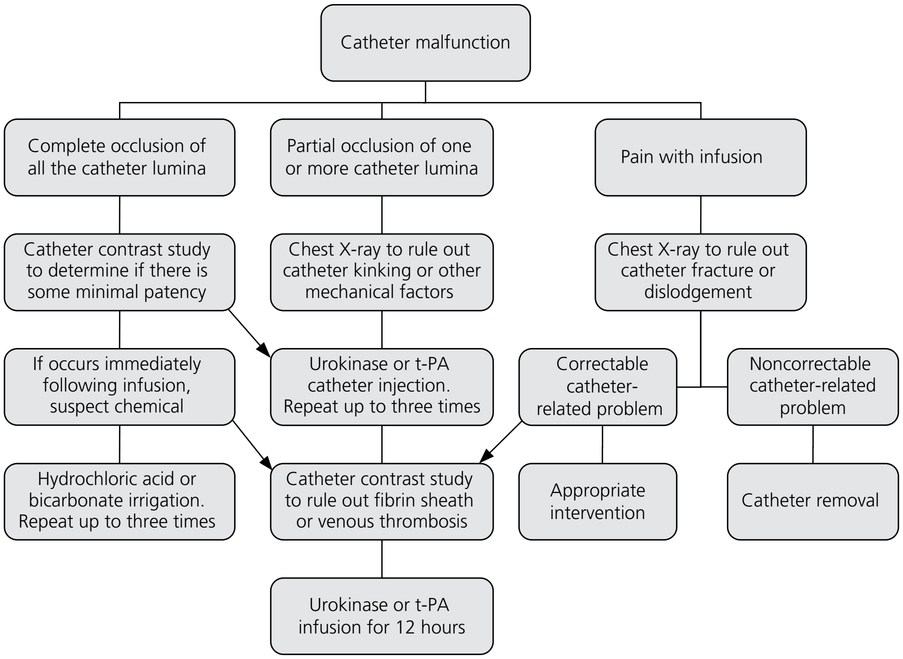
External catheters can be damaged at the site of the clamp or the suture. The use of needleless connections for infusions and irrigations should prevent needle damage. Most catheters have kits to replace the external portion of the catheter. Repair of the catheter has not been associated with an increased incidence of infection. Intravascular catheter fractures usually occur as a consequence of compression between the first rib and the clavicle (Figure 80.11). This usually can be recognized on a chest X-ray by the "pinch-off" sign [72]. Patients with this syndrome usually have intermittent and positional occlusion of the catheter flow. A segment of the catheter that embolizes into the heart or the pulmonary circulation can usually be retrieved with a snare through the femoral vein by an interventional radiologist (Figure 80.12) [73].

Drug extravasation

Accidental dislodgement of the needle from the port may lead to extravasation of the chemicals into the subcutaneous tissue. This may lead to chemical cellulitis, tissue damage, necrosis, or loss of soft tissue. Clinical signs of extravasation are changes at the infusion site with pain, burning, swelling, or erythema. If these are suspected, the infusion should be stopped and the needle withdrawn. Management of extravasation injuries depends on the type of drug infusing and on the amount extravasated. Occasionally, the patient will complain of pain along the tunnel or at the insertion site during infusion. The catheter should not be used until a contrast study has been obtained to document the catheter integrity and patency. On rare occasions, the extravasation is due to a fibrin sheath that excludes the catheter from the main lumen of the vein, causing a backflow of the solutions around the catheter to the entry site.

Catheter-related venous thrombosis

Catheter-related venous thrombosis (CRVT) can occur as a direct effect of the insertion procedure, the access site, the effect of the catheter, the location of the tip, the underlying disease, or the effect of the substances being infused. During insertion, endothelial damage initiates the coagulation cascade, which is perpetuated by the



Catheter malfunction
Complete occlusion of all the catheter lumina
Partial occlusion of one or more catheter lumina
Pain with infusion
Catheter contrast study to determine if there is some minimal patency
Chest X-ray to rule out catheter kinking or other mechanical factors
Chest X-ray to rule out catheter fracture or dislodgement
If occurs immediately following infusion, suspect chemical
Urokinase or t-PA catheter injection. Repeat up to three times
Correctable catheter-related problem
Noncorrectable catheter-related problem
Hydrochloric acid or bicarbonate irrigation. Repeat up to three times
Catheter contrast study to rule out fibrin sheath or venous thrombosis
Appropriate intervention
Catheter removal
Urokinase or t-PA infusion for 12 hours

Figure 80.10 Catheter malfunction algorithm. t-PA, tissue plasminogen activator.

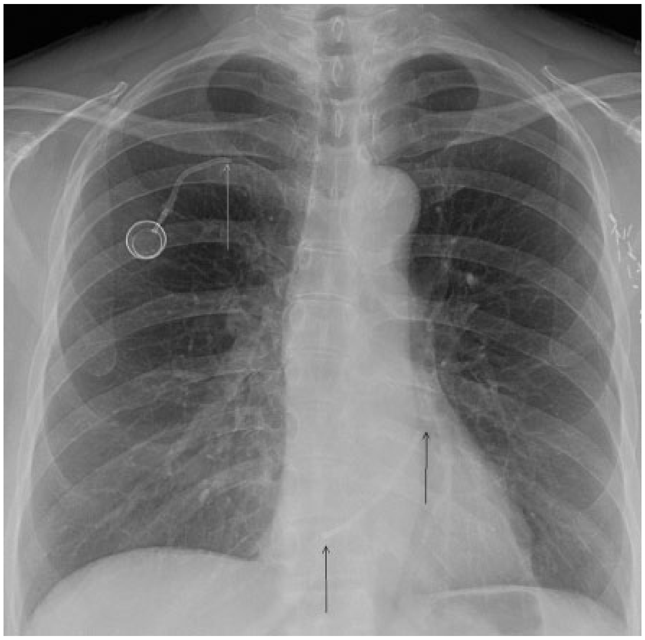


Figure 80.11 X-ray showing catheter fracture at the junction between the first rib and the clavicle with the free catheter segment in the right ventricle.

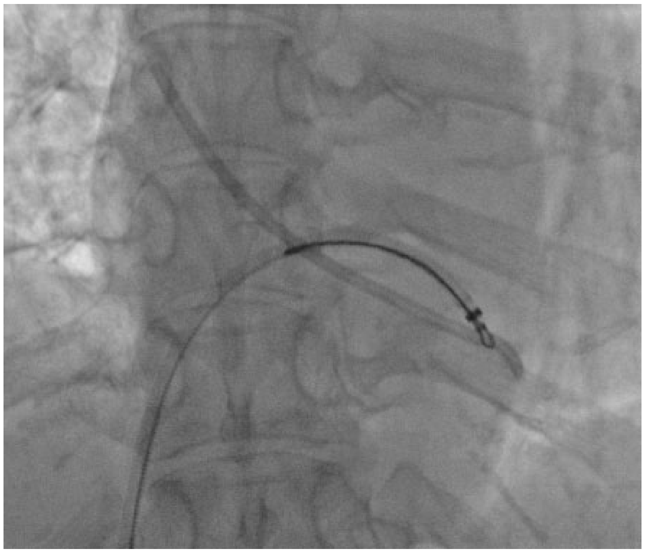

Figure 80.12 Single frame from a continuous fluoroscopy scan showing retrieval of a catheter fragment from the right ventricle using an endoloop inserted through the femoral vein.

chronic effect of the catheter in the lumen. After insertion, a mural thrombus and a fibrin sheath form around the catheter, often creating a sleeve that excludes the catheter from the true venous lumen, causing catheter malfunction [74]. Other contributing mechanical factors include the relationship between the size of the catheter and the lumen of the vein, which is particularly important in children and women. Most of the CRVTs are asymptomatic; venograms obtained in prospective studies 6 weeks after catheter placement have shown evidence of venous thrombosis in up to 36% of the patients, with only 6% of the patients reporting symptoms. The incidence of CRVT seems to be higher in older studies, which is most likely due to new insertion techniques, improvements in the compatibility of the catheter materials, and the selection of the access sites [46]. Pulmonary embolism occurs in 15–25% of patients with symptomatic CRVT and 15% develop postphlebitic syndrome. The incidence of catheter-related infections increases the incidence of catheter-related venous thrombosis in hematology patients (RR 17.6; 95% CI 4.1–74.1) [75]. Ipsilateral arm swelling, pain, and development of collaterals should alert the physician to the possibility of venous thrombosis. Venogram, computed tomography scans, and duplex Doppler venous imaging can establish the diagnosis and the site of the obstruction (Figure 80.13). The treatment should be directed at the prevention of pulmonary embolisms, avoidance of clot propagation, prevention of the postphlebitic syndrome, and preservation of the catheter whenever possible. With these considerations in mind, the catheter should be removed only if it is no longer necessary or after failure of the initial therapy. In a prospective study of 74 cancer patients with acute symptomatic deep venous thrombosis (DVT) treated with subcutaneous dalteparin 200IU/kg/day for 5–7 days and warfarin with a target international normalized ratio (INR) of 2.0–3.0, there were no episodes of recurrent venous thromboembolism and three patients (4%) had major bleeds [76]. No catheters required to be removed because of infusion failure or recurrence or extension of DVT. It is also important to note that up to 20% of patients with catheter-related venous thrombosis may have a hypercoagulable state due to inherited conditions such as a factor V Leiden gene mutation [77]. The 60-day mortality of upper extremity or internal jugular DVT is reported to be up to 30%, usually secondary to the underlying disease rather than the vein thrombosis; pulmonary embolism is seen in 3–5% of patients [78,79].

In a large meta-analysis study that included 5636 subjects from five randomized clinical trials and seven prospective studies, Saber et al. reported that the use of implanted ports decreased the incidence of CRVT compared with PICC lines (OR 0.43; 95% CI 0.23–0.80), whereas past history of DVT (OR 2.03; 95% CI 1.05–3.92), subclavian venous puncture insertion site (OR 2.16; 95% CI 1.07–4.34), and improper catheter tip location (OR 1.92; 95% CI 1.22–3.02), increased the risk of CRVT [80]. In this meta-analysis, the number of catheter lumina, the technical difficulties with catheter insertion, the use of thromboprophylaxis, current or recent exposure to estrogens, and the site of catheter insertion were not independent predictors of CRVT by multivariate analysis. There was no significant difference in the incidence in CRVT in patients with hematologic malignancies (7.7%) and solid tumors (7.5%).

There are insufficient data regarding the effectiveness of prophylactic low-dose Coumadin (warfarin sodium) or low molecular weight heparin (LMWH) in the prevention of CRVT [81]. Based on the lack of benefit in three randomized trials published in 2005 comparing LMWH or Coumadin with placebo in the prevention of CRVT, the Seventh American College of Chest Physicians Conference on Antithrombotic and Thrombolytic Therapy recommended against the use of prophylactic anticoagulation in patients with malignancy and an indwelling central venous catheter. It is also important to note that the use of heparin flush and other techniques to maintain catheter patency has not been shown to decrease CRVT. Mitchell et al. conducted a systematic review of the nonpharmacologic interventions for the prevention of CRVT [82]. Ten randomized studies met the inclusion criteria for the review; the inclusion criteria, study methodology, and objectives of the studies did not permit data meta-analysis. A Cochrane review of anticoagulation for patients with cancer and central venous catheters included

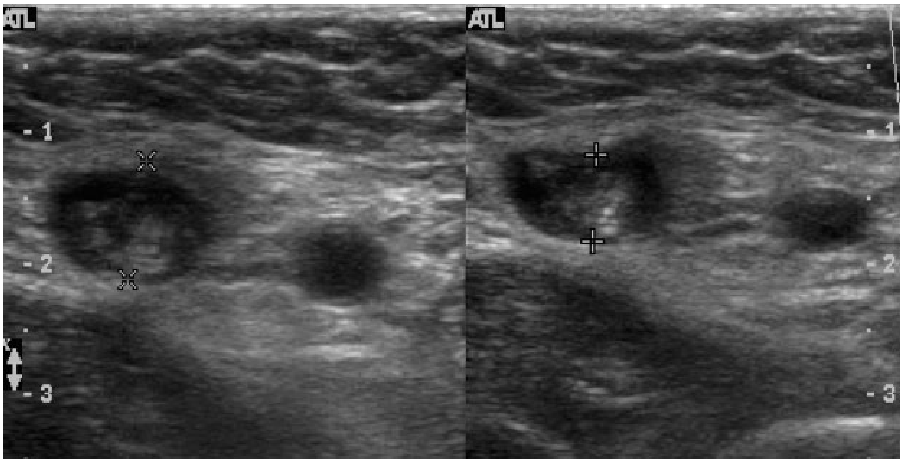

Figure 80.13 Venous ultrasound scan showing subclavian vein thrombosis on the left. Note the venous thrombus in the lumen. On the right, there is external compression of the vein with minimal change.

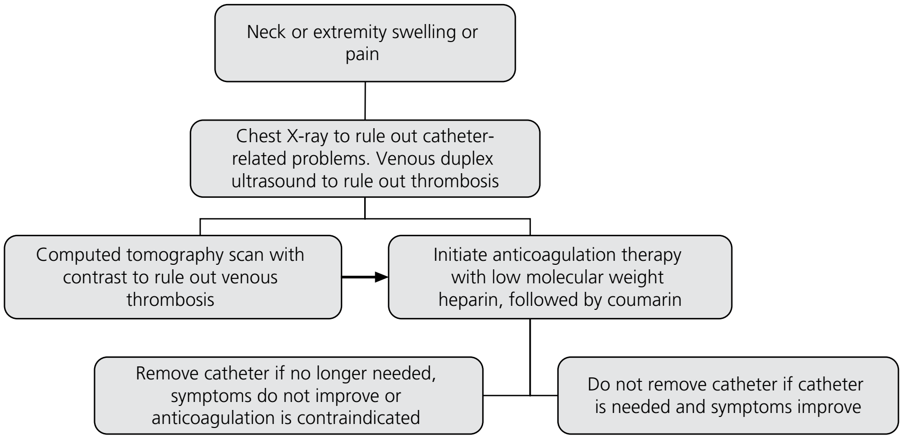
3611 patients enrolled in 12 randomized clinical trials that used prophylactic LMWH, unfractionated heparin, or vitamin K antagonist versus placebo. The review did not show any benefit of the treatment arm in the prevention of CRVT, the incidence of symptomatic DVT, major bleeding, thrombocytopenia, infection, or death [83].

Patients should be treated with systemic heparin or subcutaneous LMWH for 5–10 days prior to changing to oral anticoagulation. Continuation on LMWH should be considered for patients with a high risk for recurrent thrombosis [84]. Fibrinolytic agents are also effective in the management of this complication and seem to be associated with less postphlebitic syndrome. The incidence of catheter-related venous thrombosis [49] is associated with the catheter tip position (the more proximal, the more likely the development of venous thrombosis), the size of the catheter (especially triple lumina), and the access site (percutaneous access having a higher incidence of thrombosis than vein cutdown). The use of low-dose daily Coumadin (1 mg/day) or LMWH as a prophylaxis for catheter-related DVT remains controversial. The use of low-dose Coumadin prophylaxis has been shown to be safe in patients treated with high-dose chemotherapy and stem cell transplantation provided that the platelet count is above 50,000/dL [85]. A systematic review of the evidence showed that there is no conclusive evidence to recommend the routine use of venous thrombosis prophylaxis [86,87]. A suggested algorithm for the management of catheter-related venous thrombosis is outlined in Figure 80.14.

Catheter-related infection

CABSI and CRBSI should not be considered an unavoidable complication of cancer care. Active prevention, education, and early recognition of these complications have resulted in a steady decrease in incidence and its consequences. The Health Care Infection Control Practices Advisory Committee of the CDC has established a goal of a 100% compliance with the “central line bundle” that includes five recommendations: hand hygiene, maximum sterile barrier, chlorhexidine skin preparation, optimal site selection. and daily evaluation of the necessity for lines. Catheter-related systemic infections are potentially the most life-threatening complications, especially when they occur in the immunocompromised patient. The incidence of this complication can be significantly diminished by strictly following the catheter care protocols discussed in the previous sections. As discussed before, establishing a continuous quality improvement program to monitor and ensure compliance with established evidence-based catheter care guidelines significantly reduces the incidence of CABSI, CRBSI, and their complications [49,50]. In addition to the implementation of strict catheter care guidelines, catheter prevention efforts have focused in the use of prophylactic antibiotics at the time of insertion, the use of antibiotic–heparin lock solutions, and the use of modified catheters impregnated with antibiotics or other substances that prevent catheter colonization. The use of prophylactic antibiotics at the time of catheter insertion does not reduce the incidence of CABSI except in neutropenic patients and in patients with a previous history of CRBSI. The use of antibiotic–heparin lock solutions has been mostly studied in children; a meta-analysis of five randomized trials showed a significant reduction in CABSI but not CRBSI; it is not clear if these results can be extrapolated to the adult population and this approach is not currently recommended [88]. In recent years, considerable effort has been put into the modification of catheters by impregnating antibiotics or silver in the catheter wall or by bonding or coating the catheter with heparin, chlorhexidine, or silver sulfadiazine. Unfortunately, there is a paucity of data on the effect of antimicrobial coating or impregnation on long-term catheters in neutropenic patients. A prospective randomized study utilizing new catheter technology with silicone-impregnated catheters with minocycline and rifampin showed that these non-cuffed, non-tunneled catheters were as likely to be colonized as standard cuffed, tunneled silicone catheters [89]. In the same study, CRBSI was four times less likely to originate from antimicrobial-impregnated than from tunneled catheters (0.36 versus 1.43 per 1000 catheter-days), but the antimicrobial-impregnated catheters remained in place for a shorter period (mean 30.2 versus 43.8 days). A meta-analysis of 11,586 patients included in 37 randomized studies involving short-term placement of impregnated non-tunneled catheters showed a consistent reduction in the incidence of CRBSI with antibiotic-impregnated (RR 0.28; 95% CI 0.15–0.54) and heparin-bonded catheters (RR 0.16; 95% CI 0.06–0.43) compared with standard catheters; chlorhexidine–silver sulfadiazine-impregnated catheters failed to show a reduction in CRBSI (RR 0.80; 95% CI 0.62–1.04) [90]. The CDC recommends the use of impregnated catheters only when the implementation of a comprehensive strategy to reduce CABSI and CRBSI, including education of the healthcare personnel who insert and maintains the catheters, and the use of maximal sterile barrier precautions and chlorhexidine–alcohol skin antisepsis during central line placement fails [12].



Neck or extremity swelling or pain
Chest X-ray to rule out catheter-related problems. Venous duplex ultrasound to rule out thrombosis
Computed tomography scan with contrast to rule out venous thrombosis
Initiate anticoagulation therapy with low molecular weight heparin, followed by coumarin
Remove catheter if no longer needed, symptoms do not improve or anticoagulation is contraindicated
Do not remove catheter if catheter is needed and symptoms improve

Figure 80.14 Algorithm for venous thrombosis.

The diagnosis of a CABSI and CRBSI is very complex and varies considerably among publications [91]. The CDC defines CABSI as a bacteremia or fungemia with at least one positive peripheral blood culture in a patient with systemic clinical manifestation of infection, without another apparent infection source other than the catheter. To make the diagnosis of CRBSI, the CDC requires systemic clinical manifestations of infection with at least one positive peripheral blood culture and no apparent other source of infection. In addition, one of the following must be present:

a a positive semi quantitative [>15 colony-forming units (CFU) per catheter segment] or quantitative (>10^3CFU per catheter segment) culture, with the same organism (species and antibiogram) isolated from the catheter segment and the peripheral blood sample;

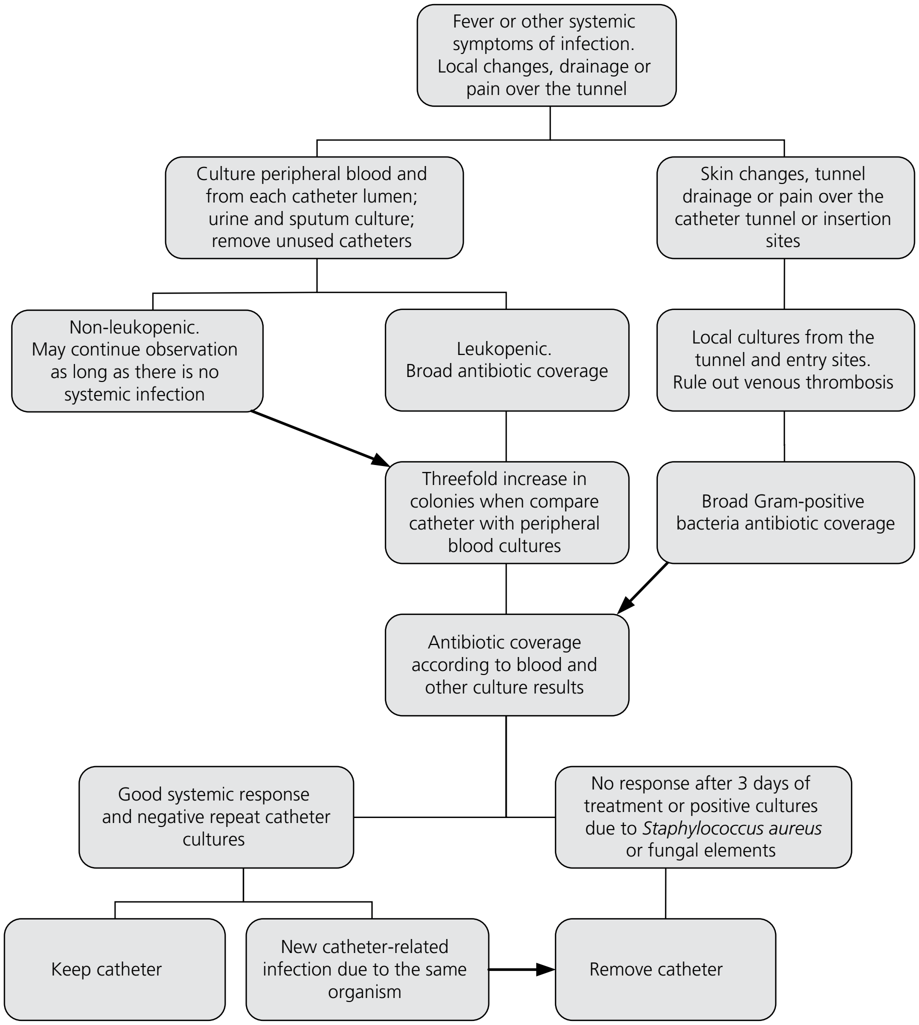
b simultaneous quantitative cultures of blood samples with a ratio of ≥3:1 (catheter versus peripheral);

c a differential period of positive blood culture from the catheter versus peripheral blood of 2 hours.

The advantage of the last two methods is that they do not require removal of the catheter to establish the diagnosis of CRBSI. Simultaneous quantitative cultures have a high specificity but are labor intensive and costly. The use of a time differential for positive blood culture between the catheter and peripheral blood of more that 2 hours has a reported 91% specificity and 94% sensitivity for the diagnosis of CRBSI [92]. The accuracy of this method requires that the same volume of blood sample is obtained from both sites and inoculated into the culture bottle.

The catheter may become colonized by the skin flora at the insertion site, from contamination of the catheter hub during external manipulation, from bacteremia from other site of infection, or from contaminated infusions. Therefore, the incidence of CABSI is related to the method and site of catheter insertion, the type of catheter, the period and degree of immunosuppression, the skin colonization, the frequency of use, the number of lumina, the type of dressing, and patient age (with a higher incidence of infections among younger patients). The incidence of CRBSI among patients with hematologic malignancies varies widely among the published studies (0–21%), depending on the definition of CRBSI used, the duration of the neutropenia, and the intensity of the treatment [46]. In a study of 213 hematology patients with short-term central venous catheters, it was shown that age was an independent risk factor for baseline skin colonization; male gender and baseline skin colonization were independent risk-predicting factors for subsequent skin colonization and positive catheter tip culture at the time of removal [93]. Several randomized studies comparing external tunneled catheters with implantable ports have failed to show differences in the incidence of infections among these devices. In a systematic review of 200 prospective studies, Maki et al. [9] reported that the incidence of catheter-related infections with external cuffed tunneled catheters was 1.6 per 1000 catheter days compared with 0.1 per 1000 catheter days for implanted ports, and 1 per 1000 catheter days for PICCs. Mollee et al. studied 1127 central venous accesses in 727 adult patients with hematologic and non-hematologic malignancies [8], and the incidence of CABSI among patients with aggressive hematologic malignancies was 7.26 per 1000 catheter days for tunneled catheters, 3.89 per 1000 days for implantable ports, and 4.22 per 1000 days for PICC lines; multivariate Cox regression identified the catheter type (higher CASBI for tunneled catheters than ports and PICC), patient diagnosis (higher CASBI for hematologic than non-hematologic malignancies), and the number of previous lines as the independent variables predictors of CASBI. This study established PICC as a reasonable option to tunneled cuffed catheters for venous access in patients with hematologic malignancies. The high incidence of CABSI in patients with hematologic malignancies compared with patients with solid tumors is not surprising, given the degree of immunosuppression, the duration of their neutropenia, and the frequency and number of catheter manipulations.

Most of the infections are secondary to Gram-positive cocci (coagulase-negative *Staphylococcus* 62%, *Staphylococcus aureus* 4%) and Gram-negative bacilli (GNB) (29%) (Enterobacteriaceae and *Pseudomonas aeruginosa*); only 4% of the infections are fungal related (*Candida*) [94]. Sometimes it is difficult to identify the source of GNB bacteremia in cancer patients. In a study of 266 patients, it was determined by multivariate analysis that infections due to *Stenotrophomonas maltophilia*, polymicrobial bacteremia, and >1000 CFU from the central line blood culture were more likely to be CRBSI, whereas in neutropenic patients, GNB bacteremia was most likely not catheter related [95]. Whenever an infection is suspected, appropriate antibiotic coverage should be instituted after the blood cultures are drawn, and antibiotic selection needs to be reassessed after the cultures are back. There are no randomized studies documenting the catheter salvage rates following antibiotic treatment. Several studies report catheter salvage rates of up to 50% following antibiotic treatment, at the expense of higher infection recurrence [96,97]. Indications for catheter removal are the persistence of symptoms or positive blood cultures after 3 days of appropriate antibiotic coverage, hypotension, severe systemic



Fever or other systemic symptoms of infection. Local changes, drainage or pain over the tunnel
Culture peripheral blood and from each catheter lumen; urine and sputum culture; remove unused catheters
Skin changes, tunnel drainage or pain over the catheter tunnel or insertion sites
Non-leukopenic. May continue observation as long as there is no systemic infection
Leukopenic. Broad antibiotic coverage
Local cultures from the tunnel and entry sites. Rule out venous thrombosis
Threefold increase in colonies when compare catheter with peripheral blood cultures
Broad Gram-positive bacteria antibiotic coverage
Antibiotic coverage according to blood and other culture results
Good systemic response and negative repeat catheter cultures
No response after 3 days of treatment or positive cultures due to *Staphylococcus aureus* or fungal elements
Keep catheter
New catheter-related infection due to the same organism
Remove catheter

Figure 80.15 Algorithm for catheter-related infection.

compromise, infections secondary to fungi or *S. aureus* (these organisms being rarely eradicated with antibiotic treatment), and recurrence of infections secondary to the same organism after successful treatment. There are limited data on what to do with patients with positive blood cultures from the catheter and negative peripheral blood cultures. Park et al. reported a retrospective review of 112 instances in 103 patients with hematologic malignancies who had only positive Hickman catheter blood cultures; 83% of them had temperatures higher than 38°C [98]. All patients received empiric antibiotic therapy; in those patients for whom the antibiotic therapy was appropriate, only 4% developed a CRBSI and 77% of the Hickman catheters were salvaged. In the patients for whom the empiric therapy did not cover the initial microbial isolate, 19% developed a CRBSI and 74% of the catheters were salvaged. A suggested algorithm for the management of catheter-related infections is outlined in Figure 80.15.

Tunnel or pocket infections are less common. The presence of swelling, tenderness, and warmth over the area is usually an indication of a local infection. In leukopenic patients, pain and fever are frequently the only symptoms. These infections are usually secondary to Gram-positive cocci. Culture of the exit site or the skin around the Huber needle will normally isolate the microorganism. Local care, removal of the Huber needle, and systemic antibiotics are measures needed in the treatment of most of these infections. *S. aureus* and fungal infections usually require removal of the catheter. The use of a second antimicrobial cuff in the external devices failed to reduce the incidence of systemic or local infections [99].

Catheter removal

There are several methods for the removal of a long-term intravenous cuffed catheter. In general, removal of the catheter and the cuff is preferred and recommended by the catheter manufacturer. This can be accomplished by catheter traction when the cuff is close to the insertion site [100]. Anesthetic infiltration around the cuff and gentle freeing of the cuff through the tunnel with a curved hemostat clamp usually help with cuff removal. When the cuff is high in the tunnel, a cutdown technique is usually necessary to remove the cuff [101]. Alternatively, a traction technique can be used, which often results in leaving the cuff behind [102]. The incidence of retained cuff infections is low and requires cuff removal [103,104]. The traction technique for catheter removal can result in fracture of the catheter at the cuff, requiring a cutdown to remove the cuff and the remainder of the catheter. The length of the fractured segment helps to determine the location of the cuff. This complication is more frequent with small-lumen and non-silicone catheters. Compression of the tunnel prevents bleeding or air embolism during the procedure.

CHAPTER 81

Pharmacologic Prevention of Acute Graft-versus-Host Disease

Nelson J. Chao
Duke University, Durham, NC, USA

Historical development

In 1955, a description of graft-versus-host disease (GVHD) in animals, then known as "secondary disease," was reported by Barnes and Loutit [1]. Named to differentiate it from the primary disease of radiation sickness, fatal secondary disease was observed in irradiated mice given allogeneic spleen cells but not in recipients of syngeneic cells. By the late 1950s, it was apparent that the skin abnormalities and diarrhea of secondary disease and runt disease (a wasting syndrome in unirradiated newborn mice given allogeneic spleen cells) were the result of immunologically competent cells introduced into an immunoincompetent host. The term graft-versus-host was introduced to describe the vector of this immunologic assault [2,3]. Early human transplants of allogeneic marrow were often complicated by GVHD [4–6]. Features were remarkably similar to those seen in animal studies of GVHD [7] and to reports of GVHD developing in immunodeficient children who had received blood transfusions [8]. Because it has been difficult to separate the illness caused by immunologic attack from the consequences of this assault (including immunodeficiency, organ dysfunction and infection), both aspects have been considered a part of human GVHD. Historically, the term *acute* GVHD describes a distinctive syndrome of dermatitis, hepatitis, and enteritis developing within 100 days of allogeneic hematopoietic cell transplantation (HCT). However, with the use of reduced-intensity conditioning (RIC) regimens, the clinical picture of acute GVHD can occur after 100 days, thus making the day 100 cut off less relevant. This distinction is not merely semantics because of the need to define these syndromes clearly in clinical trials.

Pathogenesis

In a remarkably perceptive summary in 1966, Billingham [9] defined the criteria for the development of GVHD as follows:

1. The graft must contain immunologically competent cells.
2. The host must possess important transplantation alloantigens that are lacking in the donor graft, so that the host appears foreign to the graft and is, therefore, capable of stimulating it antigenically.
3. The host itself must be incapable of mounting an effective immunologic reaction against the graft, at least for a sufficient time for the latter to manifest its immunologic capabilities; that is, it must have the security of tenure.

These criteria now require some modification to incorporate current understanding of the biology of GVHD (see Chapters 13 and 14). The occurrence of autologous GVHD suggests that inappropriate recognition of host self-antigens may occur, and transfusion-associated GVHD (T-GVHD) may develop in certain immunocompetent individuals. A multistep model of antigen expression, cytokine production, T-cell activation, and tissue injury has been described and Figure 81.1 depicts this interactive construct [10].

Alloreactivity

Abundant animal data demonstrate that T-lymphocytes contained in the donor inoculum proliferate and differentiate in vivo in response to disparate histocompatibility antigens on host tissues and directly, or through secondary mechanisms, attack recipient cells, thus producing the signs and symptoms of acute GVHD (see Chapter 13) [7,9,11]. The afferent arm of acute GVHD consists of antigen presentation, activation of T cells, clonal proliferation, and differentiation [12]. Cell death of host targets results from alloreactivity of donor-derived T cells. In the efferent phase, release of cytokines from activated lymphocytes contributes to cell death, either directly or through recruitment of secondary effectors, such as natural killer (NK) cells [13]. Based on mechanistic roles postulated for interleukin (IL)-1, IL-2, lipopolysaccharide (LPS), and proinflammatory cytokines such as IL-6, interferon (IFN)-γ, and tumor necrosis factor (TNF), immunomodulatory agents have been administered in vivo to control GVHD. The microbial environment, especially of the gastrointestinal (GI) tract, is tightly associated with this alloreactivity. Compared with conventionally housed irradiated mice, enteric GVHD was significantly reduced in germ-free mice given incompatible marrow [14]. Human studies confirmed this gnotobiotic effect [15,16]. Microorganisms likely act as triggers of GVHD by stimulating Toll-like receptors (TLRs), activating the innate immune system, sharing antigenic epitopes with gut epithelial cells, or by activating latent virus-inducing antigens on cell surfaces to become targets of alloreactivity [17]. Gut damage could also lead to leakage of LPS into the circulation, thereby releasing cytokine effectors of GVHD [18]. The research into the human microbiome is an exciting field, especially with recent data from murine and human transplantation demonstrating significant changes in specific bowel flora when measured by ribosomal 16S RNA sequencing [19]. These data suggest the potential for manipulating the bowel flora as one mechanism for reducing intestinal inflammation and GVHD.

Predictive factors

Some of the predictive factors have been utilized as targets for agents in the prevention of GVHD. HLA disparity between the hematopoietic cell donor and recipient is the most powerful factor governing the severity and kinetics of GVHD. The importance of class I and II allele matching in reducing the risk for GVHD has been widely demonstrated in unrelated donor HCT cohorts [20]. In a National Marrow Donor Program (NMDP) analysis of individuals undergoing HCT from HLA-A and -B-matched unrelated donors, HLA-DRB1 allele disparity was independently associated with an increased risk of severe acute GVHD [21]. Further studies have determined the effects of HLA matching (low or high resolution or both) on engraftment, GVHD, and mortality in 1874 donor–recipient pairs retrospectively typed at high resolution for HLA-A, -B, -C, -DRB1, -DQ, and -DP. Mismatches at HLA-A, -B, -C, and -DRB1 each had similar adverse effects on mortality. These adverse effects on outcome were more evident in transplants with low-resolution versus only high-resolution mismatches. Mismatches for HLA-DQ or -DP did not significantly affect outcome. When high-resolution mismatches at HLA-A, -B, -C, and -DRB1 were considered together, adverse effects on survival and GVHD were observed [22]. Minor HLA peptides have been identified and sequenced, and minor histocompatibility antigen (mHA) disparities appear correlated with the risk for GVHD in adults given HLA-identical donor grafts [23,24]. The importance of mHA matching is further supported by the observed low rate of GVHD in populations that feature genetic homogeneity [25]. Sex mismatching and donor parity have been associated with an increased risk of acute GVHD [26]. Female donor T cells could recognize H-Y minor antigens on host Y chromosome-containing cells. Moreover, previously parous donors could have experienced alloimmunization as a result of unshared minor antigens of the fetus [27].

Age is another key factor, with younger patients experiencing less acute GVHD [26,28]. Moreover, using older matched unrelated donors has led to a higher incidence of GVHD in the recipients. The source of allogeneic hematopoietic cells may also influence the development of GVHD. For more than two decades, experience was derived from marrow transplant cohorts describing rates and risk factors for GVHD [6,26]. Virtually all marrow grafts were infused as fresh products, although one group reported an apparent reduction in rates of GVHD with cryopreserved marrow [29].

Of considerable interest to stem-cell biologists, umbilical cord blood cells appear less immunologically reactive than bone marrow cells [30]. When utilized in HCT, there is a lower rate of GVHD, especially since many are donor–recipient pairs are not HLA matched [31,32]. Allogeneic peripheral blood progenitor cells (PBPCs) have become a more common source for HCT and associated with an increased risk for chronic GVHD appears [33]. Faster engraftment, fewer hospitalizations, less donor morbidity, and economic advantages are noted with the use of peripheral blood. A meta-analysis of 16 studies (five randomized and 11 cohort) found that the relative risk (RR) for acute GVHD after PBPC transplantation was 1.16-fold greater ($p = 0.006$) compared with bone marrow transplantation (BMT) [34]. In a cohort study of PBPC compared with BMT from unrelated donors, GVHD rates were similar but non-relapse mortality (NRM) was lower and survival was higher after PBPC transplantation (see Chapter 41) [35]. A prospective randomized study conducted by the Bone Marrow Transplant Clinical Trials Network (BMT CTN) demonstrated an increase in chronic GVHD with the use of PBPC with no survival advantage [36]. One interpretation of these data suggests that patients with a lower risk of relapse would benefit from marrow rather than PBPC since there would be less chronic GVHD.

Studies of CD34$^+$ cell dose have shown advantages in resource utilization and cost in autologous HCT. In allogeneic PBPC transplantation, a higher hematopoietic cell dose ($6.3–10 \times 10^6$ CD34$^+$ cells/kg) was associated with a sharp increase in GVHD risk among cyclosporine (CSP) recipients. In contrast, CD34$^+$ cell dose did not appear to influence the occurrence or severity of acute or chronic GVHD in allogeneic BMT [37]. Of interest, a low PBPC dose ($<3 \times 10^6$ CD34$^+$ cells/kg) was associated with slower hematologic recovery, increased rates of fungal infections and NRM, and decreased overall survival.

As shown in Figure 81.1, activated donor T cells release proinflammatory cytokines which upregulate HLA expression (see Chapter 13). One report found that the genotype in the donor of IL-1 receptor antagonist (allele 2) was protective against severe GVHD developing in the recipient [38]. Single nucleotide polymorphisms were determined in sibling transplants and recipient genotypes for IFN-γ intron 1, IL-10^{-1064} and TNF d3 were found to be associated with acute GVHD, whereas IL-6^{174} genotype was associated with chronic GVHD [39]. In a similar study of genetic and clinical factors, polymorphisms of IL-10 in both donor (RR 3.5) and recipient (RR 7.9) predicted for acute GVHD along with donor cytomegalovirus (CMV) seropositivity and mHA mismatching. More recently, polymorphisms in the innate immunity gene (*NOD2/Card15*) have also been associated with chronic GVHD. A recent genome-wide scan of 40 previously reported candidate single-nucleotide polymorphisms (SNPs) demonstrated only a few associations with GVHD [40]. Use of imputed genotypes to replicate previous IL-10 associations was validated, as was the IL-6 donor genotype. The donor genotype was associated with a 60% increase in risk for grade III–IV acute GVHD after related HCT (adjusted $p = 0.028$).

The incidence of acute GVHD after matched sibling HCT varies inversely with the efficacy of post-transplant immunosuppressive prophylaxis and with the intensity of the preparatory regimen. Multivariate analysis revealed that an increased dose of pre-transplant total body irradiation (TBI) was associated with an increased risk of GVHD. Among HLA-identical HCT recipients who received GVHD prophylaxis with methotrexate (MTX) and CSP, acute GVHD developed in 48% of patients given 1575 cGy TBI, compared with 21% of patients given 1200 cGy TBI ($p = 0.02$) [41]. One hypothesis is that more intensive myeloablative conditioning might eliminate persisting host cells and restrict the development of mixed donor–host chimerism, which has been associated with a decreased probability of GVHD [42]. Alternatively, more intensive conditioning could increase GI damage, modify the microbial environment, release cytokine mediators, and/or attenuate the dose of administered GVHD prophylaxis. Some studies have indicated that donor or host infection (as denoted by seropositivity for the herpesviruses) predicts the subsequent development of GVHD [43], whereas others found no predictive association [44].

Prophylaxis of GVHD had consisted of the most commonly utilized immune suppressive drugs. These drugs were initially used as single agents and then in combination. These drugs are discussed individually below; however, the efficacy for prophylaxis of GVHD relies on combination of these agents. Table 81.1 summarizes the available randomized studies using these drugs.

It is important to point out that the diagnosis of GVHD is a clinical one with the pathology helping sometimes in confirming the diagnosis. Therefore, the overall grading based on clinical findings is a potential methodologic problem in GVHD prevention trials. There can be significant inter-observer differences at a single institution. Moreover, there are significant differences between institutions as to what is determined to be, for example, grade II acute GVHD. Efforts to find biomarkers for GVHD are ongoing and would help considerably in future trials. For example, the elevation of REG3α seems to be associated with lower GI and liver acute GVHD [45]. The drugs utilized for the prevention of GVHD are discussed individually below and are broadly outlined in Figure 81.2.

Non-specific immunosuppressive drugs

Corticosteroids

This class of drug has been combined with other immunosuppressants in prophylaxis against GVHD, but is most frequently used as front-line therapy in the treatment of established GVHD.

Pharmacology

The most commonly utilized corticosteroid is methylprednisolone (MP), which differs from prednisolone and prednisone only by the addition of a 6α-methyl group. The 6α-methyl group blocks the specific binding of this corticosteroid to transcortin, the plasma protein that carries steroids. Instead, MP is primarily bound to albumin. The frequent side effects from MP may be dependent on the albumin level in the host. The lack of transcortin binding leads to a higher partition coefficient and the result is a significantly greater penetration into bronchial alveolar fluids, which may provide a therapeutic advantage for the treatment of pulmonary inflammatory states.

Signaling by the steroid molecules is achieved through binding to a specific cytosolic receptor, thereby initiating its pharmacologic effects (Figure 81.3). This binding of steroid to receptor activates the complex, enabling it to translocate rapidly into the nucleus. There it is associated with specific sequences known as the glucocorticoid response elements (GREs). These response elements regulate the mRNA expression of certain proteins, leading to the known biologic effects. Generally, larger doses produce greater intensity and duration of effects. The utility of corticosteroids in GVHD is thought to be related to its lympholytic activity. The presumed activity is that corticosteroids destroy many but not all lymphoid cells. Hence other mechanisms, such as down-modulation of cytokines, are also likely to be responsible [46]. There are data to suggest that the major effect of corticosteroids is the suppression of proinflammatory cytokines rather than direct cellular cytotoxicity of lymphocytes [47]. In clinical trials that measured cytokines, the levels of TNF-α decreased after the initiation of corticosteroids used for the therapy of GVHD [48].

Toxicity

There are many adverse effects associated with corticosteroids. In addition to their immunosuppressive effects, which set the stage for infectious complications, most of the adverse effects are related to Cushingoid features, hyperglycemia, fluid retention, hypertension, occasional psychosis or neurotoxicity, and myopathy. Other chronic effects such as osteoporosis, cataract formation, and aseptic necrosis also occur. Corticosteroids are sensitive to a variety of drug interactions, specifically with anticonvulsants, which may increase the total clearance of unbound corticosteroids.

Clinical use

The drug of choice has been MP followed by oral prednisone when patients are able to eat sufficiently or when a patient's diarrhea has resolved so that one can be confident that they will absorb the medication without difficulty. One regimen, which combines CSP, MTX, and prednisone (beginning after all MTX doses have been administered), is among the most potent combinations for the prevention of acute GVHD, resulting in only 9% grade II–IV acute GVHD in the best transplant candidates (patients in first remission of acute leukemia or first chronic phase of chronic myeloid leukemia) for allogeneic BMT [49]. The doses of MP given for prophylaxis have varied and most GVHD prevention regimens do not include corticosteroids. In support of the delayed use of corticosteroids are the results noted in a prospective randomized study comparing CSP, MTX, and MP versus CSP and MTX in patients receiving BMT from an HLA-identical sibling [50]. MTX was given in four doses (on days 1, 3, 6, and 11), and MP was not begun until day 14. Acute GVHD was more common in the patients treated without MP. This study also noted no difference in relapse or in chronic GVHD. However, a second randomized study found no difference between these two regimens in preventing either acute or chronic GVHD [51]. Based on these data, our current recommendation is to save the use of corticosteroids for the treatment of acute GVHD.

Most prophylactic regimens taper the steroid dose to zero by +180 days. When steroids have been used for the treatment of acute GVHD, the usual methylprednisolone dose is 1–2 mg/kg administered in divided doses with a tapering schedule after about 2 weeks of 10% every 3–5 days. Occasionally higher pulse doses of up to 10 mg/kg have been used. Chronic GVHD treatment dose is started in the region of 1 mg/kg on a daily basis. The goal thereafter is to switch patients to an alternating day regimen to spare the side effects of corticosteroids [52]. For older patients, a small dose of prednisone, similar to those used in autoimmune diseases, may be necessary to suppress reactivation of GVHD.

Corticosteroids have also been used as local treatment for GVHD using oral beclomethasone 17,21-dipropionate (BDP), a synthetic diester of beclomethasone, a corticosteroid analog that has appeal in the treatment of GI GVHD by virtue of its ability to direct therapy to inflamed GI mucosa [53]. Patients were randomized to receive prednisone for 10 days plus either BDP (8 mg/day) or placebo for 50 days. The results of this study demonstrated that oral BDP was more effective than placebo in restoring oral intake in patients with grade II GVHD with GI symptoms, and allows prednisone to be rapidly tapered without a flare of intestinal symptoms. Importantly, there was a survival advantage for those on BDP that lasted past the first year of randomization. Unfortunately, a second confirmatory randomized study did not replicate the initial data.

The complex of the drug and receptor translocates efficiently into the nucleus where it interacts with glucocorticoid response elements (GREs), leading to the generation of messenger RNA and protein synthesis.

Methotrexate (MTX)

MTX is an analog of aminopterin, the folic acid antagonist introduced in 1948 for the treatment of acute leukemia**.** The precise mechanism by which MTX prevents GVHD is not understood; however, it is likely related to MTX's ability to inhibit cellular growth and division. Therefore, antigen-activated T cells that are rapidly proliferating would be particularly sensitive to this antimetabolite. MTX can induce tolerance following marrow transplantation. In canine transplantation, MTX given after the graft was effective in controlling GVHD and in inducing tolerance when donor and recipient were matched for the dog leukocyte antigen system [54].

Pharmacology

At the cellular level, MTX exerts its cytotoxic effect by inhibiting dihydrofolate reductase (DHFR). DHFR is the intracellular enzyme responsible for converting folic acid to reduced folate cofactors. The reduced state of the folates, namely the tetrahydrofolates, are responsible for the transport of single carbon groups that are required for purine and thymidylate synthesis. Once the single carbon group has been delivered, the oxidized folates must be converted back to tetrahydrofolates by DHFR. MTX binds to DHFR, thereby preventing its ability to reduce the oxidized folates to tetrahydrofolate and blocking further purine or thymidylate synthesis.

Following the administration of MTX, approximately 50% is bound to plasma proteins, especially albumin, with the highest tissue-plasma equilibrium reported in the kidney, liver, GI tract, and muscle. The GI tract is an important site of distribution and metabolism of MTX, perhaps accounting for one of the primary sites of toxicity. One concern in using MTX is its clearance in those patients who have pleural or ascitic fluid since these reservoir spaces can have a substantial impact on the disposition of MTX. These spaces can be a reservoir from which MTX can be continuously released, leading to severe toxicity. At the low intravenous (IV) doses, MTX clearance correlates with glomerular filtration, and renal excretion of unmetabolized drug is the major route for elimination.

Polyglutamate formation is also important to MTX metabolism [55]. The formation of MTX polyglutamates intracellularly may account for its retention within the cell and its cytotoxic effects. The enzyme folyl polyglutamate synthetase adds glutamate residues to folates or antifolates such as MTX. The polyglutamate derivatives of MTX appear to be as toxic to DHFR as the native compound. If the retained MTX polyglutamates are produced differentially in lymphocytes compared with other normal cells, the effective concentrations of the drug would differ. For example, these differences in intracellular concentrations may account for selective toxicities and may selectively inhibit certain subpopulations of cells [56].

Toxicity

The most common adverse effects of MTX when used for GVHD prophylaxis are hematopoietic, renal, hepatic, and GI mucosal toxicity. Patients may have an elevation of creatinine and bilirubin levels following the administration of MTX. As many of these are also the side effects of CSP or tacrolimus, dose attenuation of MTX and CSP or tacrolimus may be necessary. Full target doses may not be achievable in patients with grade III–IV mucositis resulting from the preparatory regimen because of airway obstruction and severe oropharyngeal bleeding.

Clinical use

The use of MTX following allogeneic BMT has been exclusively with the IV formulation. The drug doses administered have been relatively small, given the inability to dose escalate MTX significantly (Table 81.2). Initial studies in Seattle tested MTX as a single agent on a weekly basis up to day +100 but, because of the toxicity of weekly administration of MTX, the dose was changed to four doses and combined with CSP [57]. MTX, when used with CSP or tacrolimus, generally is injected IV on days 1, 3, 6, and 11 following BMT. This schema is currently the most commonly utilized prophylaxis regimen. Another schema that is commonly used following unrelated stem-cell transplantation has been named “mini-dose MTX,” usually used in conjunction with tacrolimus [58]. In this regimen, MTX is given on days 1, 3, 6, and 11 at 5 mg/m^2. The overall prevention of GVHD was similar to that of standard dose MTX with lower systemic toxicities. In general, patients should be very well hydrated, have their urine alkalinized with sodium bicarbonate until the urine pH is 8 or above. Moreover, dose attenuation should be considered for elevations of creatinine, bilirubin, and grade III–IV mucositis. One suggested schema for dose attenuation of MTX is shown in Table 81.3. There has been one report of leucovorin rescue after MTX [59]. In this small series, the use of leucovorin was not associated with an adverse outcome, although this practice is not commonly used. Leucovorin circumvents the blocked tetrahydrofolate synthesis by supplying reduced folates directly, therefore bypassing the blocked DHFR.

Specific T-cell immunosuppressive drugs

Cyclosporine (CSP)

CSP, also known as cyclosporin A, has led to a considerable expansion of the field of allogeneic transplantation given its potent immunosuppressive activity. CSP is a cyclic peptide, first extracted in 1969 from two strains of fungi isolated from soil samples. CSP was tested as an antifungal agent and demonstrated only limited effects, but it was highly effective as an immunosuppressive agent. These studies led to it being administered to patients in 1978 [60].

Pharmacology

CSP is a neutral hydrophobic cyclic peptide composed of 11 amino acids (Figure 81.4). Over the past decade, much work has been devoted to understanding the mechanism of CSP’s activity. Moreover, CSP, as well as tacrolimus, has been used as a chemical probe to dissect the pathways of T-cell activation. Although CSP and tacrolimus are distinct in their molecular structures (Figure 81.4), their mechanisms of action will be discussed together since they are almost indistinguishable in their cellular functions. What is known thus far is that CSP, and tacrolimus, block the calcium-dependent signal transduction pathways distal to engagement of the T-cell receptor (TCR) (Figure 81.5). This block interrupts the activation of T cells since the signaling from the TCR is prevented. In dissecting the signaling pathway, several critical intracellular molecules have been identified and include calmodulin, calcineurin, and the nuclear factor of activated T cells (NF-AT). The activation cascade includes calcium binding to calmodulin, which leads to binding calcineurin. The activated calcineurin may dephosphorylate the cytoplasmic unit of NF-AT, which allows translocation of the NF-AT from the cytoplasm into the nucleus to form a competent transcriptional activator of the *IL-2* gene [61].

Table 81.2 Outline of some regimens used for graft-vs.-host disease (GVHD) prophylaxis

CSP			MTX[a]		
Day	**Dose (mg/kg)**	**Route**	**Day**	**Dose (mg/m^2)**	**Route**
−2 to +3	5	IV QD over 20 h	+1	15	IV

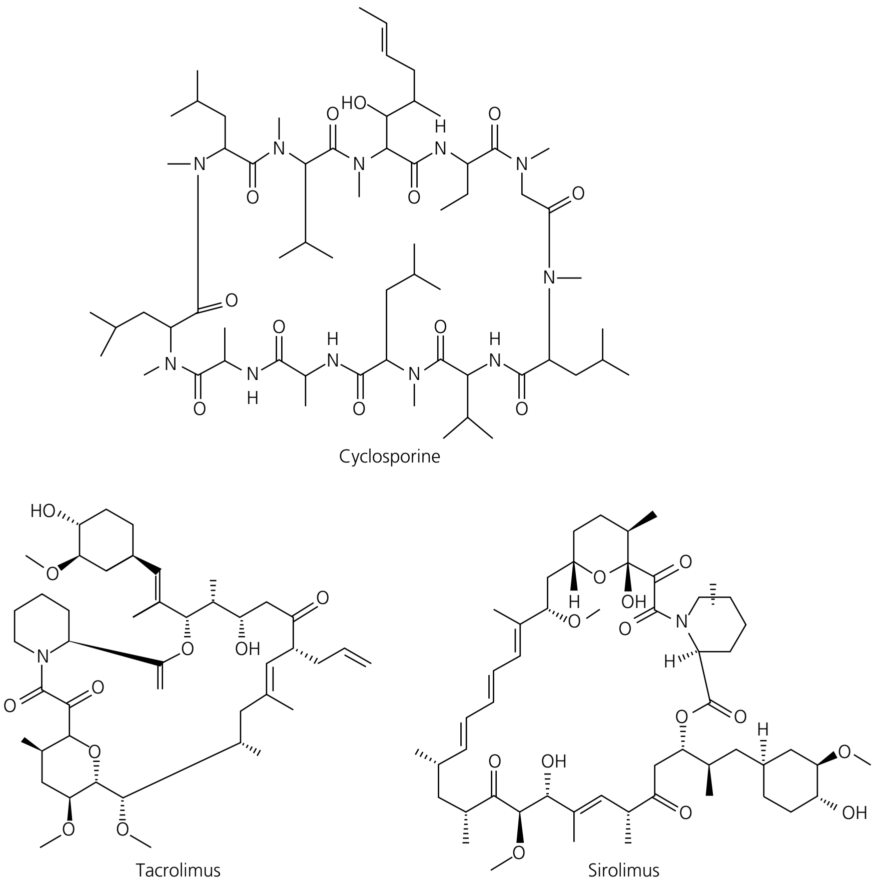
<1.5	100
1.5–1.7	75
1.8–2.0	50
>2.0	Hold dose

The cytosolic binding protein for CSP was isolated in 1984 from lymphocytes and named cyclophilin for its high affinity for CSP [61]. The analogous major isoform of the binding protein



Cyclosporine

Tacrolimus

Sirolimus

Figure 81.4 Structures of cyclosporine (CSP), tacrolimus, and sirolimus.

for tacrolimus has been termed tacrolimus binding protein (FKBP). Both cyclophilin and FKBP are highly basic and very abundant in the cytoplasm. Although these two proteins do not have sequence homology, they both function as the enzyme prolyl *cis–trans*-isomerase (or rotamase) [62]. Rotamase accelerates the conversion of *cis* and *trans* rotamers of proline-containing peptides or proteins. This conversion step is thought to be the rate-limiting step during normal protein folding. Both of these molecules are potent inhibitors of rotamase activity. The binding of CSP or tacrolimus to these rotamases suggests that inhibition of this enzyme may be an important step leading to immunosuppression. The mechanism of action of CSP is exerted through binding to cyclophilin (as tacrolimus is bound to FKBP). This complex of drug and binding protein interrupts the activation cascade at the level of NF-AT dephosphorylation, and therefore NF-AT is not able to enter the nuclear domain and activate the IL-2 gene (Figure 81.5).

CSP is a highly lipophilic drug that is extensively metabolized with subsequent biliary and, to a lesser extent, urinary secretion. Over 15 metabolites have been isolated and identified. Some metabolites also have immunosuppressive activity while others are nephrotoxic. Thus, the clinical efficacy and interactions between CSP and the other drugs may be confounded by its metabolites. However, the most commonly reported inhibition or induction of CSP metabolism is by cytochrome p450 enzymes, specifically HLp and PCN1 enzymes that are members of the cytochrome P450 IIIA gene family [63].

Toxicity

The major clinical toxicities that need to be monitored with CSP administration are renal insufficiency and elevation of bilirubin levels. Both of these complications appear to be dose related. The acute nephrotoxicity is due to vasoconstriction and ischemia of the afferent arterioles in the kidney. These acute changes are reversible but if present for too long can lead to an irreversible interstitial injury with glomerular thrombosis resulting in permanent azotemia. A major difficulty clinically is to differentiate specific side effects of CSP from those of other drugs such as amphotericin, MTX, and aminoglycoside or from an underlying disease process such as GVHD. Other side effects that are commonly encountered are hypertension, hyperglycemia, headaches, and hirsutism. Rarer events include gum hypertrophy, brittle nails, acne, nausea, and vomiting. One specific clinical concern is the apparent association of hypomagnesemia and seizures in patients on CSP. Many patients who have a seizure while on CSP may also have concurrent hypomagnesemia and hypertension. Correction of these two abnormal findings is important in the management of patients. Hypertension alone can occasionally become a significant problem. Usually nifedipine is the drug of choice since it is an effective antihypertensive, and it has not been associated with changes in the CSP levels. A rare but potentially reversible toxicity associated with CSP is posterior reversible encephalopathy syndrome (PRES) [64]. The clinical syndrome is characterized by headaches, confusion or decreased consciousness, visual complaints, and seizures. There are commonly associated findings of posterior cerebral white matter

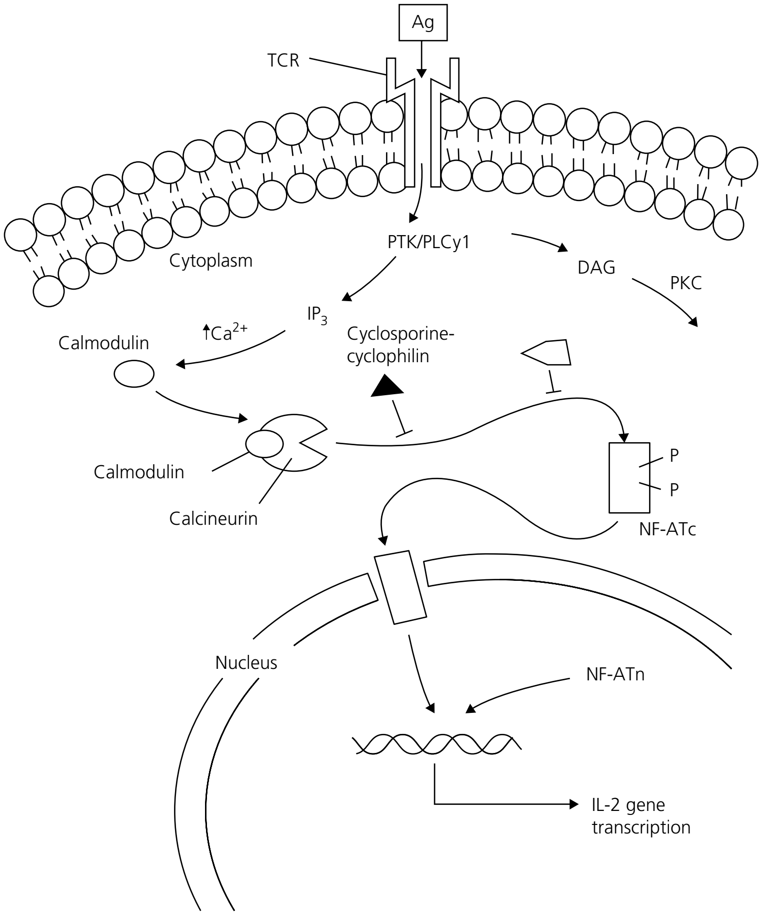


Figure 81.5 Simplified diagram of the signal transduction found in the activation of a T cell through the T-cell receptor (TCR) and the point where cyclosporine (CSP) and tacrolimus interact with its binding proteins to block the generation of nuclear factor of activated T cells (NF-AT) and its subsequent generation of interleukin 2 (IL-2). Sirolimus, although similar to tacrolimus in structure, does not inhibit the signaling through the TCR but rather inhibits signaling through the CD28/B7 family of molecules and prevents the egress of cells from the G_1 phase. DAG, diacylglycerol; IP3, inositol triphosphate; PKC, protein kinase C; PLC, phospholipase C; PTK, protein tyrosine kinase.

vasogenic edema in studies such as magnetic resonance imaging (MRI). Prompt recognition is important, so that the findings can be reversed. CSP should be stopped and treatment of the hypertension and seizures (if present) instituted. A different immunosuppressant should be used in lieu of restarting CSP. Another rare but important toxicity of CSP (and tacrolimus) is the induction of a hemolytic uremic syndrome (HUS)/thrombotic thrombocytopenic purpura (TTP) syndrome. Patients present with schistocytes and elevated creatinine with or without mental status changes. In some circumstances, this toxicity will abate if one calcineurin inhibitor is substituted for the other.

Clinical use

CSP can be administered IV or orally. It is initially administered IV since in the early phase following transplantation many patients develop mucositis and GI damage from the preparatory regimen and also from MTX given for GVHD prophylaxis. Once the patient is eating and drinking without significant difficulties CSP may be switched to an oral preparation. CSP is available as an olive oil solution and as soft gelatin capsules in addition to the microencapsulated form. CSP is erratically and incompletely absorbed after oral administration, with many factors reported to influence oral CSP bioavailability. For example, food intake may impact its absorption, especially if the meal is high in fat content. The absorption kinetics of CSP have been described as either of zero order or a series of first-order processes. CSP dosage usually is governed by research protocols, beginning the drug at a higher dose as a "loading dose," with a gradual taper over time. However, there are several variations of dosing schedules. An example of a CSP regimen in given in Table 81.2.

There have been several studies attempting to correlate the efficacy of prophylactic CSP with its level in either whole blood, plasma, or serum. Although the specific analytic methods are clearly more precise and preferable to the non-specific methods for therapeutic drug monitoring, the technical difficulties with current high-performance liquid chromatographic methods make it less practical to utilize it widely. Moreover, there are limited data to suggest that there is a correlation between CSP levels and clinical outcome. The results from these studies suggest that there may be a complex relationship between dose, blood level, and occurrence of GVHD [65,66]. These studies failed to demonstrate a clear direct correlation between drug level and occurrence of GVHD.

From a practical standpoint, CSP is administered to achieve a "therapeutic level" but, beyond that, it is important to deliver the planned dose per protocol. It is also important to be certain that the level drawn is a trough level in the steady state, otherwise the values will not be interpretable. CSP levels are used to increase the dose if it is below the therapeutic threshold. In general practice, the dose is not decreased for elevated levels if no toxicity is present, but if the level is above twice the upper limit of the therapeutic range, then it is reasonable to decrease the dose to avoid potential neurotoxicity (i.e. seizures). There are also concerns about the possible interactions between CSP and other medications. Many different drugs have been implicated in increasing or decreasing CSP levels in patients. Such medications and their effects are listed in Table 81.4 [67,68].

Table 81.4 Cyclosporine (CSP) drug interactions

Decrease CSP levels	Increase CSP levels[a]

	Alcohol
	Colchicine
	Fluoroquinolones
	Imipenim

[a] Not all macrolides are identical in effects because some do not form stable complexes with cytochrome P450 enzymes.

Tacrolimus (FK506)

Tacrolimus is a macrolide antibiotic extracted from the soil fungus *Streptomyces tsukubaensis* [69]. It is completely different from the cyclic peptide CSP, but it does exhibit a very similar selective immunosuppressive activity (Figure 81.4). Its mechanism of action is also through the inhibition of signaling through the TCR (Figure 81.5).

Pharmacology

Tacrolimus is highly lipophilic, and its method of administration is similar to that of CSP. Its mechanism of action has been reviewed above in conjunction with CSP. It is generally given IV in the early phases following allogeneic transplantation and then switched to the oral formulation. There is rapid distribution of the drug to the central compartment after a short IV infusion. Following oral administration, tacrolimus is erratically and incompletely absorbed [70]. The major difference from CSP is that the absorption of tacrolimus does not seem to depend on the presence of bile salts. Tacrolimus undergoes extensive distribution with the highest levels found in the lung, kidney, heart, and spleen. While in the blood, it is distributed into red blood cells. Less than 1% of the IV or oral dose appears unchanged in the urine, indicating that the drug is almost completely metabolized in the liver prior to its elimination. It is eliminated primarily through monodemethylation, dimethylation, and hydroxylation. The half-life of tacrolimus is approximately 9 hours and longer in those patients who have hepatic dysfunction. Tacrolimus is monitored in a similar fashion to CSP. Appropriate doses and levels of tacrolimus have not yet been clearly defined in patients undergoing allogeneic BMT, but the general blood levels have been 10–20 ng/dL.

Toxicity

Tacrolimus is moderately well tolerated in humans. Most of the data on adverse events can be categorized into neurotoxicity, renal toxicity, and hyperglycemia and generally have been reported in solid organ transplantation recipients. Tacrolimus can cause an increase in serum creatinine concentration similar to that of CSP, probably secondary to a decrease in glomerular filtration. Hypertension in previously normotensive patients has also been described. Occasionally hypertension can be refractory to antihypertensive medication. The most commonly utilized antihypertensives have included the calcium channel blockers. Central nervous system (CNS) effects have also been found, including headaches, tremors, parathesias, photophobia, mental status changes and PRES. Other findings include pulmonary symptoms such as dyspnea, musculoskeletal pain, itching, GI complaints (including anorexia, nausea, vomiting, and abdominal pains), and fatigue. Although the adverse effects of CSP and tacrolimus appear to be similar, there may be some advantage of tacrolimus in hypertensive patients. Hyperkalemia has also been observed following tacrolimus administration.

Clinical use

Tacrolimus has been evaluated in combination with MTX for the prevention of GVHD. In a multicenter trial, 329 recipients of HLA-identical marrow transplants were randomized to receive a short course of MTX plus either tacrolimus or CSP [71]. The incidence of grade II–IV acute GVHD was significantly lower in patients who received tacrolimus (32% vs. 44% with CSP), even though more unfavorable patients were enrolled in the tacrolimus group. This difference was largely due to a reduction in grade II disease. The incidence of chronic GVHD was similar in the two groups (56% and 49%), but severe chronic disease was more likely with CSP. There were, however, surprising adverse findings in the tacrolimus group:

1. There was inferior 2-year survival (41% vs. 50% with CSP) and overall survival (47% vs. 57% with CSP) that was largely due to poorer survival of patients with advanced disease (25% vs. 42%).
2. There was a higher incidence of regimen-related adverse events, which predominantly occurred in patients with advanced disease.

The conclusion of the study was that in patients without advanced disease, tacrolimus plus MTX was more effective than CSP plus MTX in the prevention of acute GVHD, with no difference in disease-free or overall survival. The survival disadvantage in patients with advanced disease warrants further study.

Another randomized trial also compared tacrolimus plus MTX with CSP plus MTX [72]. Tacrolimus was more effective than CSP for the prophylaxis of acute GVHD but there was no difference in patient survival or relapse. Although these trials were performed in patients with HLA-identical marrow transplants, uncontrolled [73–75] and controlled [76] observations indicated that tacrolimus also has activity against acute GVHD in recipients of matched unrelated donor transplants. The doses used in GVHD prophylaxis trials begin at 0.03–0.04 mg/kg/day as a continuous infusion. When patients are able to sustain near normal oral food and fluid intake, the drug is given orally at a dose of 0.15 mg/kg/day administered in two divided doses.

Sirolimus (rapamycin)

Sirolimus is a lipophilic macrolide that was identified more than 20 years ago during an antibiotic screening [77]. This molecule is produced by a strain of *Streptomyces hygroscopicus* isolated from a soil sample from Easter Island (Rapa Nui). Although lacking antibacterial activity, it inhibited yeast growth and growth of filamentous fungi. The first demonstration of sirolimus's immunosuppressive activity was obtained from studies demonstrating the inhibition of immunoglobulin E (IgE) production and also efficacy in experimental allergic encephalomyelitis and adjuvant arthritis [77]. The interest in sirolimus as an immunosuppressive agent coincided with the discovery of the immunosuppressive activity of tacrolimus since the structures of both of these molecules contained a distinctive hemiketal-masked α,β-diketopipecolic acid amidic component (Figure 81.4).

Pharmacology

Sirolimus binds to the same family of intracellular receptors as tacrolimus, termed tacrolimus binding proteins (FKBPs). In a similar fashion to tacrolimus, sirolimus has two domains, a domain bound by FKBP and an effector domain forming a composite surface that interacts with the mammalian target of sirolimus. The intracellular target of sirolimus [termed the mammalian target of rapamycin (MTOR)] is ubiquitously expressed in human tissue, with the highest level found in the testes and skeletal muscle.

Although sirolimus and tacrolimus bind to the same family of intracellular binding proteins, the mechanisms of immunosuppression are clearly distinct. Sirolimus inhibits the growth of hematopoietic and lymphoid cells in vitro. The most striking observation is that it suppresses cytokine-driven growth of these cells. The data demonstrate a significant increase in the proportion of G_1 phase cells when sirolimus is added [78]. The mechanism of action of sirolimus is to inhibit specifically the progression of cells from G_1 into the S phase, suggesting that it may interfere with the signaling that is critical for the cyclin/cyclin-dependent kinase (CDK) complex required for cellular proliferation. Data using human peripheral blood T cells demonstrate that the block of G_1 may be related to an increase in a species of titratable inhibitor of G_1 cyclin/CDK [79]. In addition to regulation of the cell cycle, sirolimus may also exert an effect in signal transduction pathways that mediates specific cytokine responses. For example, sirolimus has been shown to inhibit IL-1-driven IFN-γ production [80]. Moreover, the secondary signals required for T-cell activation and proliferation are dependent on ligation of the B7 family with CD28. Lack of the secondary signal has been shown to result in anergy in the responding T cell. While signaling through the TCR is not affected by sirolimus, signaling through CD28 is inhibited by sirolimus [81]. CD28 signaling leads to a sustained downregulation of the inhibitor I kappa B (IκB). CD28-mediated downregulation of IκB-α is prevented by sirolimus. These data suggest that sirolimus affects the CD28 signaling pathway, which may be a significant mechanism of its action and distinct from either CSP or tacrolimus. Moreover, in murine experimental models sirolimus has been shown to expand selectively naturally occurring $CD4^+CD25^+Foxp3^+$ regulatory T cells (Tregs) in vivo [82]. Sirolimus has also been used to expand these cells ex vivo for cellular therapies directed against activated T cells. This approach is being tested in patients as a method to prevent GVHD.

Toxicity

Sirolimus appears toxic to the GI system, including elevation of liver function tests and diarrhea. In contrast to the renal side effects that are common with CSP and tacrolimus, nephrotoxicity is rarely encountered with sirolimus. However, sirolimus may potentiate the nephrotoxicity of CSP [83]. Other toxicities of sirolimus include hypertriglyceridemia, a decrease in platelets and leukocytes, epistaxis, blood pressure changes, headaches, nausea, mucous membrane irritation, and infections. The use of sirolimus at high doses may also increase the risk of hepatic sinusoidal obstruction syndrome (SOS) [84]. Adverse reactions previously observed with other macrolide antibiotics are also of concern. Testicular atrophy has been observed in both mice and non-human primates. These early observations suggest that liver function abnormalities, thrombocytopenia, and neutropenia may be its dose-limiting toxicity.

A retrospective review of 488 patients studied the effect of treatment with sirolimus on the incidence of SOS [84]. When used with cyclophosphamide/total body irradiation (CY/TBI) conditioning, sirolimus was associated with a significantly increased incidence of SOS [odds ratio (OR) 2.35]. The concomitant use of MTX further increased this rate (OR 3.23), whereas sirolimus without MTX was not associated with a significantly increased risk of SOS (OR 1.55). Overall treatment-related mortality was lowest when sirolimus was used without MTX. When used with busulfan-based conditioning, sirolimus was associated with an even higher rate of SOS (OR 8.8). These data suggest that myeloablative doses of busulfan should not be used with sirolimus-based immunosuppression [85].

Clinical use

Sirolimus has been used as the front-line regimen for the prevention of GVHD in combination with tacrolimus and low-dose MTX for GVHD prophylaxis in mismatched related donor and mismatched unrelated donor HCT [86]. All evaluable patients engrafted. An absolute neutrophil count of 500/µL was achieved on day +18 (range, 11–32 days). Sustained platelet counts of more than 20,000/µL were attained on day +29 (range, 14–98 days). Grades 0–I acute GVHD occurred in 75% of patients. Grade II, III, and IV acute GVHD occurred in 13, 8, and 5%, respectively (total grade II–IV GVHD, 26%). It was concluded that sirolimus was tolerable, adequate blood levels were achievable, and there was a low rate of acute GVHD compared with historical data in this high-risk population.

A second study explored sirolimus and tacrolimus without MTX following matched related donor (MRD) and matched unrelated donor (URD) HCT [87]. No overall differences between the 53 MRD and 30 URD transplants were noted. Engraftment was rapid, with median times to neutrophil and platelet engraftment of 14 and 12 days, respectively. The incidences of grade II–IV and grade III–IV acute GVHD were 20 and 5%, respectively; the cumulative incidence of chronic GVHD was 59%. The 30- and 100-day treatment-related mortalities were 0 and 4.8%, respectively.

This regimen was tested formally in a randomized phase III study in the MRD population comparing tacrolimus/sirolimus with tacrolimus/MTX in a trial conducted by the Bone Marrow Transplant Clinical Trials Network (BMT CTN). A total of 304 patients were randomized, comparing sirolimus/tacrolimus with tacrolimus/MTX. The overall data suggested less mucositis with sirolimus/tacrolimus but no differences in GVHD or survival [88].

Mycophenolate mofetil

Mycophenolate mofetil (MMF) is a morpholinoethyl ester of mycophenolic acid (MPA). MPA is produced by several species of *Penicillium* molds and this agent possesses antibacterial, antifungal, antiviral, antitumor, and immunosuppressive properties. MMF's immunosuppressive activity occurs after hydrolysis to MPA. Therefore, MPA is the active moiety but it is formulated as MMF to enhance its bioavailability. MMF inhibits the proliferation of T and B cells and the production of antibodies [89]. Most of the clinical data are in the solid organ literature. The developmental work on MMF has utilized the dog model in BMT. Studies in the dog model of allogeneic transplantation by Storb et al. [90] demonstrated that the combination of MMF and CSP was highly effective at the prevention of host-versus-graft rejection and graft-versus-host reaction following a reduced-intensity conditioning regimen. These studies led to a marked increase in this form of transplantation worldwide. The contribution of MMF to the development of this approach was significant.

Pharmacology

Purines are essential for the growth and survival of cells. Cells have two pathways to produce purines: de novo and salvage pathways. Lymphocytes are highly dependent on the de novo synthesis whereas other cells can utilize both (Figure 81.6). In the de novo pathway, the ribose-phosphate portion of the purine nucleotide is derived from 5-phosphoribosyl-1-pyrophosphate, which is derived from adenosine triphosphate and the sugar ribose-5-phosphate. Therefore, 5-phosphoribosyl-1-pyrophosphate is an essential intermediate in the synthesis of purines. Following T-cell stimulation, there is a brisk and sustained increase in 5-phosphoribosyl-1-pyrophosphate and guanosines, and deoxyguanosines activate 5-phosphoribosyl-1-pyrophosphate synthetase. Therefore, depletion of guanosines would lead to a decrease in 5-phosphoribosyl-1-pyrophosphate synthetase and inhibition of purine synthesis, which is required for T-cell activation. MPA action is through the inhibition of inosine monophosphate dehydrogenase (IMPDH). This enzyme catalyzes the oxidation of inosine monophosphate to xanthine monophosphate. Xanthine monophosphate is a required intermediate metabolite in the synthesis of guanosine triphosphate. The enzyme IMPDH is a critical enzyme for the de novo biosynthesis of purine nucleotides, specifically guanosine monophosphate (GMP). Blockade of GMP synthesis leads to a negative feedback inhibition of 5-phosphoribosyl-1-pyrophosphate and prevention of T-cell activation. The therapeutic index of MMF depends on the lymphocytes' reliance on de novo synthesis of purines, allowing for greater immunosuppressive activity with less toxicity.

Toxicity

MMF does not seem to deplete GTP in neutrophils, in contrast to lymphocytes and monocytes. Its selective action on lymphocytes seems to spare the higher risk of acute infections. The major side effect of MMF has been suppression of the hematopoietic system with neutropenia. GI side effects including GI bleeding have also been reported occasionally. Different preparations differ in the degree of GI toxicity. Doses of up to 1.5 g twice daily had no nephrotoxicity, myelosuppression, or other serious side effects in patients with rheumatoid arthritis. The use of MMF has also been associated with progressive multifocal leukoencephalopathy (PML), and a "black box" warning to this effect has been issued by the US Food and Drug Administration (FDA). Methods for monitoring drug levels of MMF are available, although it is not yet clear how these tests should be utilized. One study demonstrated that the median bioavailability of MMF was 72%, with eightfold variability [91]. There was also the suggestion from this study that three times daily dosing may be more advantageous.

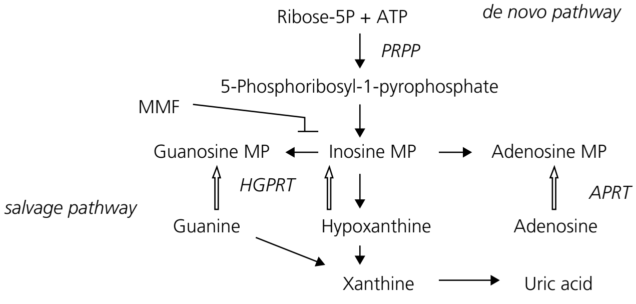

Figure 81.6 The salvage and de novo pathway of purine synthesis. Inositol monophosphate (IMP) is at a central position and mycophenolate mofetil (MMF) inhibits IMP dehydrogenase, necessary for the conversion of inosine MP to guanosine MP. HGPRTase, hypoxanthine–guanine phosphoribosyltransferase; PRPP, 5-phosphoriboxyl-1-pyrophosphate, APRT, adenine phosphoribosyltransferase.

Clinical use

MMF has been used as part of the front-line regimen for the prevention of GVHD especially within the setting of reduced-intensity preparatory regimens. This drug is commonly used as part of the post-transplant immune suppression as there are data in the dog model that it supports donor cell engraftment. It is possible that the prolonged administration of MMF helps to delay the onset of GVHD since the use of MMF instead of MTX as immunosuppressive therapy led to a delay of the onset of GVHD after reduced-intensity HCT. However, preliminary results of a prospective trial in which MMF was given twice daily for 27 days in combination with CSP suggested that this combination is not superior to the standard regimen of MTX plus CSP for preventing GVHD after ablative HCT from related and unrelated donors [92]. In this study, the median time to engraftment after hematopoietic cell transplantation was 15 days (range, 10–20 days). The incidence of acute GVHD was 62%, which was comparable to that in a group of historical controls receiving CSP and MTX for GVHD prophylaxis. Although a significant improvement in the prevention of GVHD was not suggested, compared with CSP and MTX, MMF in combination with CSP could be considered in cases in which MTX is contraindicated.

Cyclophosphamide

Cyclophosphamide and its nitrogen mustard-derived alkylating agent ifosfamide were developed by Norbert Brock and ASTA-Werke after synthesizing more that 1000 candidate compounds in the 1950s. The goal was to convert the base nitrogen mustard into a non-toxic prodrug form (also called latent drug) so that it could be given intravenously with less toxicity. Once inside the cells, the prodrug would be converted into the active toxic form. It is chemically an oxazaphosphorine and was the first of the prodrugs designed for cancer therapy.

Pharmacology

Given that cyclophosphamide is a prodrug, it is converted by mixed-function oxidase enzymes found in the liver. The main metabolite is 4-hydroxycyclophosphamide (historically used in purging studies of the bone marrow in autologous HCT), which is the active moiety. Another active metabolite is phosphoramide mustard, which can be formed from the tautomer of 4-hydroxycyclophosphamide, aldophosphoramide. This metabolite is only formed in cells that have low levels of aldehyde dehydrogenase (ALDH). Aldophosphoramide is converted to phosphoramide mustard and acrolein (the cause of hemorrhagic cystitis). Phosphoramide mustard forms DNA cross-links both between and within DNA strands at guanine N-7 positions leading to inter- and intrastrand cross-linkages. Since these cross-links are irreversible, the cell is unable to divide and cell death occurs.

Toxicity

Cyclophosphamide has relatively little typical chemotherapy toxicity as ALDHs are present in relatively high concentrations in bone marrow stem cells, liver, and intestinal epithelium. ALDHs protect these actively proliferating tissues against toxic effects by converting aldophosphamide to carboxyphosphamide rather than the toxic metabolites phosphoramide mustard and acrolein. It is the high levels of ALDH in the marrow that allow its use after an ablative regimen for HCT. Adverse drug reactions include chemotherapy-induced nausea and vomiting, bone marrow suppression, diarrhea, darkening of the skin/nails, alopecia or thinning of hair, changes in color and texture of the hair, and lethargy. At high doses of cyclophosphamide, hemorrhagic myocarditis can occur with high mortality. Hemorrhagic cystitis is a frequent complication, but this can be prevented by adequate fluid intake and mesna (sodium 2-mercaptoethane sulfonate), a sulfhydryl donor that binds acrolein.

Clinical use

Earlier studies had shown that high-dose cyclophosphamide given post-transplantation along with tacrolimus and MMF was safe and effective in preventing graft rejection and GVHD after non-myeloablative conditioning and transplantation of T-cell-replete bone marrow from partially HLA-mismatched related donors [93,94]. These results suggested the feasibility of a phase I/II study to evaluate the effectiveness of single-agent high-dose cyclophosphamide in reducing the incidence of acute and chronic GVHD following myeloablative allogeneic HCT. All patients (78 HLA-matched related and 39 HLA-matched unrelated donors) received conventional myeloablation using busulfan plus cyclophosphamide conditioning and T-cell-replete bone marrow, followed by 50 mg/kg per day of cyclophosphamide on days 3 and 4 post-transplantation [94]. The incidences of grade II–IV and grade III–IV acute GVHD were 43 and 10%, respectively, and the day-100 and 2-year non-relapse mortalities were 9 and 17%, respectively. At a median follow-up of 26 months among surviving patients, the cumulative incidence of chronic GVHD was 10%. These data suggest that, in the majority of patients, this use of cyclophosphamide after transplantation results in selective removal of alloreactive donor T cells, with the most dramatic effect being the low incidence of chronic GVHD. These results are being expanded and repeated in other centers for a more definitive conclusion.

Antibodies

Many antibodies have been used for the prevention and treatment of GVHD. Most of the promising data have come from studies using selected monoclonal antibodies directed at specific epitopes. However, these antibodies are not generally available and most of the studies have involved small groups of patients. Several antibodies will be discussed, namely intravenous immunoglobulin (IVIg), anti-CD3, antithymocyte globulin (ATG), daclizumab or basiliximab (anti-IL-2 receptor), infliximab (anti-TNF-α receptor), etanercept (soluble TNF receptor), and alemtuzumab (Campath 1H).

Anti-CD3

OKT3 is an anti-CD3 monoclonal antibody that is commercially available. This antibody has been used to treat GVHD, but because it is a stimulatory antibody to the T cell, the results have not been uniformly successful. Carpenter et al. showed that soluble antihuman CD3 monoclonal antibodies induce apoptosis of activated T cells [95]. They evaluated different anti-CD3 antibodies and demonstrated that the ability to induce apoptosis varied among them. Compared with OKT3, one monoclonal antibody termed HuM291 induced more sustained phosphorylation of ERK-2, greater release of IFN-γ, and more activation-induced T-cell death. The use of HuM291 (visilizumab) in a phase I study in patients with steroid refractory acute GVHD was highly encouraging. This antibody is not capable of cross-linking with Fc receptors on accessory cells and therefore does not activate proliferation of T cells. In one study, of the 17 enrolled patients, five achieved a complete resolution of GVHD, eight had partial improvement, two showed no change, and two progressed. Eight of the 13 responders had sustained responses, but the estimated 1-year survival was only 24%. Epstein–Barr virus (EBV) reactivation was also a problem and therefore monitoring for EBV is important with early intervention with rituximab if necessary.

Intravenous immunoglobulin (IVIg)

Polyclonal human immunoglobulins purified and sterilized from serum pooled from many donors have been used to manipulate the immune system. There are many preparations of IVIg with different titers of anticytomegalovirus activity. To date there are no known clinical differences with the use of any of these commercial preparations. Occasionally, one preparation may be preferable to another based on the need to conserve the volume that a patient receives. The initial studies focused on its use to prevent infectious complications following BMT [96,97]. However, in a large randomized trial of IVIg, this product was also associated with a decrease in the incidence of GVHD, especially in BMT recipients under the age of 20 years. Moreover, there was a decrease in the overall mortality in favor of those who had received IVIg [98]. Although this agent is effective in the early phase following BMT, its prolonged use, in the absence of hypogammaglobulinemia after day +100, does not reduce late complications or chronic GVHD and may be associated with impairment of humoral immune recovery. Moreover, serious issues such as the extremely high costs of these products and occasional limited availability have led to a decrease in their use.

Antithymocyte globulin

Antithymocyte globulin (ATG) is a polyclonal immunoglobulin prepared by injecting horses (Atgam) or rabbits (Thymoglobulin) with human thymocytes or with a T-cell line (Fresenius). These antibodies are capable of destroying human leukocytes. The half-life of these antibodies differs significantly between the horse and rabbit ATG and the functional half-life of these antibodies is not well defined, although rabbit ATG is more potent than horse ATG. ATG has been used as part of the preparatory regimen prior to infusion of donor cells to decrease the incidence of graft rejection or following BMT to prevent GVHD. In two prospective studies using ATG as part of GVHD prophylaxis, ATG was not effective [99,100]. Prospective and retrospective studies have had mixed results regarding the efficacy and safety of various ATG preparations for the prevention of GVHD. In a report of 109 patients enrolled in two randomized trials from Italy, use of rabbit ATG in patients undergoing unrelated donor transplants reduced the incidence of both severe acute and extensive chronic GVHD [101]. However, this did not translate into a reduction in treatment-related mortality because of an increase in fatal infections in the ATG treatment arm.

Another trial randomly assigned 202 patients undergoing allogeneic HCT from matched unrelated donors to receive GVHD prophylaxis with CSP plus MTX, with or without rabbit ATG [102]. The addition of ATG significantly reduced the overall incidence of acute and chronic GVHD, without an increase in relapse or non-relapse mortality, and without compromising overall survival. However, addition of ATG did not significantly reduce the incidence of grade III–IV acute GVHD or death within 100 days, the primary end-points of the study. A subsequent report of this study demonstrated a lower incidence and severity of chronic GVHD without increasing the risk of relapse [103]. Patients treated with ATG were more likely to have undergone successful taper of other immunosuppressants.

A retrospective analysis of 1676 adults undergoing reduced-intensity HCT for hematologic malignancy compared outcomes among patients who underwent in vivo T-cell depletion with ATG (584 patients) or alemtuzumab (213 patients) with those of patients who did not undergo T-cell depletion [104]. When compared with T-cell-replete transplantation, ATG resulted in similar rates of acute GVHD; lower rates of chronic GVHD (40% versus 52%), higher rates of relapse (49% versus 38%), and lower overall survival (38% versus 50%) at 3 years.

These studies suggest that ATG is effective in decreasing the rate of acute and chronic GVHD in patients undergoing HCT, but that these benefits do not translate as yet into a survival benefit. The efficacy and safety of ATG are likely affected by the intensity of the preparative regimen. Since ATG is a foreign xenogeneic protein and an antibody, serum sickness can occur. Corticosteroids, acetaminophen, and H1 and H2 blockers are frequently used to prevent or treat the symptoms associated with the infusion of ATG. The use of ATG after BMT has been associated with an increase in lymphoproliferative disorders [105].

Anticytokine therapy

Several cytokines have been implicated in GVHD. IL-2 is a critical molecule in T-cell survival and stimulation. There are two monoclonal antibodies in clinical use directed against the IL-2α receptor (daclizumab) and also a chimeric anti-IL-2 monoclonal antibody (basiliximab) [106]. The bulk of the data have been obtained from solid organ allograft rejection studies. The use of anticytokine agents in stem-cell transplantation is limited. The initial results of the use of dacluzimab are encouraging, although these are phase II data and further studies are necessary to confirm these results. As with all antibodies, toxicities associated with such proteins are common and include myalgia, fevers, rash, pruritus, arthritis, and headaches. Further caution is warranted in targeting the IL-2 receptor since CD25 is also expressed in regulatory T cells. In a prospective study with contemporaneous controls, the use of an immunotoxin directed against this epitope resulted in a higher incidence of acute GVHD [107]. The data suggested that CSP blocked the induction of CD25 expression on alloreactive T cells but had no detectable effect on CD25 expression on regulatory T cells, thus enhancing the loss of regulatory T cells.

TNF is another cytokine that has been implicated in acute GVHD. Use of a polyclonal neutralizing antibody against TNF-α resulted in a 70% reduction in GVHD-associated mortality and also in diminished lesions in the skin and the intestines in an experimental model [108]. Similar findings were observed using a neutralizing antibody against murine TNF with reduction of splenomegaly in GVHD models. Higher TNF levels have also been described in those patients who develop GVHD, although this finding has not been universally observed [109]. There are two anti-TNF molecules. Infliximab is a chimeric monoclonal antibody that binds to TNF. There is also a fusion molecule, etanercept, that consists of the soluble TNF receptor (p75) linked to the Fc portion of human IgG_1 (TNFR:Fc) [110]. These molecules are successful in the therapy of Crohn disease and rheumantoid arthritis and could be equally useful following allogeneic BMT, but well-designed studies will be necessary. There are preliminary data for the use of infliximab in the therapy of acute GVHD, but these data have not been reported in the peer-reviewed literature.

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody directed against CD52. This antibody was formerly known as Campath-1H and is active against early- and late-stage chronic lymphoid leukemia and also T-cell prolymphocytic leukemia. Alemtuzumab targets the 21–28-kDa cell surface glycoprotein CD52, a protein present on the surface of mature lymphocytes but not on lymphoid progenitors. The function of CD52 is unknown, but it is found on >95% of peripheral blood lymphocytes and monocytes. Upon binding to CD52, alemtuzumab initiates its cytotoxic effect by complement fixation and antibody-dependent cell-mediated cytotoxicity mechanisms [111].

Alemtuzumab has been associated with frequent infusion-related events, including hypotension, rigors, fever, shortness of breath, bronchospasm, chills, and/or rash. These side effects necessitate close follow-up of the patient, especially in their first dose infusion. Other serious infusion-related events have been reported: syncope, pulmonary infiltrates, adult respiratory distress syndrome, respiratory arrest, cardiac arrhythmias, myocardial infarction, and cardiac arrest. An important and potentially fatal complication of therapy with alemtuzumab is the increased risk for opportunistic infections, in particular, reactivation of cytomegalovirus.

Several groups have utilized this monoclonal antibody as a backbone to a preparatory regimen in reduced-intensity conditioning to decrease GVHD. The first report of using alemtuzumab in a reduced-intensity conditioning regimen was investigated in 44 patients with hematologic malignancies [112]. Forty-two of the 43 evaluable patients had sustained engraftment. There were no cases of grade III–IV acute GVHD. Only two patients developed grade II acute GVHD, and only one had chronic GVHD. The estimated probability of non-relapse mortality was low at 11%. These data suggested that inclusion of alemtuzumab in a reduced-intensity preparative regimen is associated with durable engraftment, minimal toxicity, and low incidence of GVHD. The use of this monoclonal antibody has been extended for use in haploidentical hematopoietic cell transplantation [113]. In a standard-risk group of 19 patients with aplasia or in remission at transplantation there was a 1-year survival rate of 63% [95% confidence interval (CI), 38–80%] and median overall survival time of 2.9 years (95% CI, 6.2–48 months). While some groups have used this monoclonal antibody as a backbone of their preparatory regimen, it is not used universally because of concerns regarding infections and relapses.

Other agents

Induction of anergy

An exciting approach for the prevention of GVHD is to induce tolerance by inhibition of costimulatory molecules. To this end, the use of a chimeric molecule, CTLA4-Ig, has been investigated. Data generated from studies of T-cell activation have clearly demonstrated that there is a critical need for a second costimulatory signal for a positive immune response. Lack of secondary signals results in specific T-cell anergy. CTLA-4-Ig is a fusion protein designed in an attempt to prevent costimulation signals. Variable results have been observed using the CTLA-4-Ig fusion protein to block GVHD across major histocompatibility barriers [114]. These results may vary according to the model of GVHD selected (i.e. major histocompatibility differences) or the activation state of T cells. Methods to block costimulation hold significant promise in achieving antigen-specific unresponsiveness or anergy and therefore a state of tolerance [115]. In a clinical trial of tolerance induction, haploidentical bone marrow was treated ex vivo with CTLA-4-Ig in the presence of recipient peripheral blood [116]. The laboratory parameters such as T-cell precursor frequency against allogeneic targets were markedly reduced. The preliminary clinical data were encouraging, with a low incidence of GVHD and encouraging overall survival. Such new approaches may circumvent the need for prolonged immunosuppression after BMT and may be clinically beneficial for patients who require an allogeneic BMT.

Photopheresis/pentostatin

The use of extracorporeal photopheresis or pentostatin is a choice for patients with chronic GVHD. This combination approach has been explored as a means to induce tolerance in a reduced-intensity preparatory regimen. Patients received a preparative regimen of photopheresis, pentostatin, and TBI followed by allogeneic stem-cell infusion from 6/6 or 5/6 HLA-matched related donors or 6/6 HLA-matched unrelated donors. GVHD prophylaxis consisted of cyclosporin A and a short course of MTX. Sixteen of 18 patients developed full donor chimerism with no day-100 transplant-related mortality. Grade II–IV acute GVHD and extensive chronic GVHD developed in 19% and 18% of patients, respectively. At a median follow-up of 14 months (range, 1–35 months), the 1-year failure-free and overall survival were 64% and 65%, respectively [117].

Conclusion

This chapter has focused primarily on the most frequently used drugs for immunosuppression or immunomodulation for GVHD (Table 81.5). As we learn more about the impact of the human microbiome, especially of the gut and skin, effector cell trafficking to target organs of GVHD, more directed therapy to impact the gut flora, adhesion molecules, and homing receptors may be developed [118]. Because GVHD and solid organ rejection remain such a difficult clinical problem, there is a need for continued efforts to develop novel immunosuppressive or immunomodulatory agents. As shown in Table 81.1, the number of randomized controlled trials for the prevention of acute GVHD has been modest over the past 30 years. Moreover, there is only one agent approved by the FDA for GVHD prevention (Gamimune). Well-designed randomized trials in this complex disorder are critical for advances in the control of GVHD [119].

Table 81.5 Immunosuppressive drugs, targets, and mechanisms of action discussed in this chapter

Drug	Target	Mechanism of action
Corticosteroids	Steroid receptor	Multiple, including cytokine expression, lymphocyte activation, and cell depletion
MTX	DHFR	Blocks DNA synthesis
CSP	Calcineurin	Blocks lymphocyte activation
Tacrolimus	Calcineurin	Blocks lymphocyte activation
Sirolimus	MTOR	Blocks costimulatory signal and cell division
MPA	IMPD	Blocks DNA synthesis
Dacluzimab/basiliximab	IL-2 receptor	Blocks lymphocyte activation
IVIg	Multiple	Unknown
ATG	Multiple	Blocks lymphocyte activation
Infliximab	TNF receptor	Blocks lymphocyte activation
Etanercept	TNF	Blocks lymphocyte activation
Thalidomide	Unknown	Unknown
Clofazimine	Unknown	Unknown
Hydroxychloroquine	TAP proteins	Blocks lymphocyte activation
CD4-D1 peptide	CD4	Blocks lymphocyte activation
CTLA-4-Ig	CD28	Blocks lymphocyte activation

ATG, antithymocyte globulin; CSP, cyclosporine; DHFR, dihydrofolate reductase; IL, interleukin; IMPD, inosine monophosphate dehydrogenase; IVIg, intravenous immunoglobulin; MHC, major histocompatibility complex; MPA, mycophenolic acid; MTX, methotrexate.

CHAPTER 82

T-cell Depletion to Prevent Graft-versus-Host Disease

Robert J. Soiffer
Dana Farber Cancer Institute, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

Introduction

Acute and chronic graft-versus-host disease (GVHD) account for a significant fraction of the morbidity and mortality associated with allogeneic hematopoietic cell transplantation (HCT) [1]. GVHD reduces survival directly as a result of organ damage and indirectly as a consequence of infectious complications prompted by GVHD prophylaxis and therapy. Donor T-cell depletion (TCD), when it was initially introduced, offered the potential for prevention of GVHD without the toxicity associated with immune suppressive drugs. Numerous TCD methods have been utilized over the past three decades. These have included ex vivo negative selection approaches (e.g. monoclonal antibody, elutriation, lectin agglutination, or photodepletion techniques), ex vivo positive selection through CD34$^+$ columns, or in vivo administration of anti-T cell antibody preparations such as antithymocyte globulin (ATG) and alemtuzumab (Table 82.1). Most early trials documented that TCD could substantially limit acute and chronic GVHD. However, this reduction in GVHD did not translate into improved overall survival (OS) because of unexpected high rates of graft failure [2], Epstein–Barr virus-associated lymphoproliferative disorders (EBV-LPDs) [3], and disease recurrence [4,5] following TCD-HCT. There have been very few randomized studies evaluating TCD, but those that have been performed have not demonstrated a survival advantage to this approach [6]. Nonetheless, there still remains substantial interest in perfecting the technique, particularly to limit the long-term consequences of acute and chronic GVHD and to permit HCT across human leukocyte antigen (HLA) barriers.

Early preclinical models of T-cell depletion

In the 1950s, Barnes and Loutit noted that following irradiation of mice, infusion of isologous marrow and spleen led to long-lasting survival, whereas inoculation of allogeneic cells afforded only a temporary recovery, with most animals later succumbing to a wasting condition called "secondary phase of irradiation syndrome" [7]. They subsequently proposed that this "secondary disease" was the result of a graft-versus-host immunologic response. Uphoff demonstrated that this GVHD did not develop after infusion of fetal liver/spleen tissue, which lack mature T-lymphocytes [8]. In the 1960s, Bortin and Saltzstein extended Uphoff's findings and further demonstrated that irradiated mice given allogeneic embryonic liver and thymus cells became true chimeras that did not reject donor skin grafts [9]. These pivotal observations pointed to the critical connection between mature donor T-lymphocytes and GVHD, and suggested that selective in vitro removal of these cells from the allograft could prevent this transplant complication.

In 1968, van Dicke et al. reported on the use of differential centrifugation on a discontinuous albumin gradient to separate lymphocytes from hematopoietic precursors, and demonstrated that irradiated mice given spleen cell fractions devoid of small lymphocytes resulted in 80–100% survival without evidence of GVHD. In contrast, all mice inoculated with fractions that contained increasing numbers of small lymphocytes died from severe GVHD [10]. Subsequently, Reisner et al. demonstrated that mouse bone marrow and spleen cell suspensions, when treated with soybean and/or peanut agglutinin, could generate an agglutinated fraction that is enriched in hematopoietic activity but depleted of T cells. Treatment of irradiated mice with this fraction conferred hematopoietic recovery with a low incidence of GVHD [11].

In the 1970s, absorbed antisera with retained activity against mature lymphocytes were developed and successfully used in animal models as the method for ex vivo T-cell depletion. Mice, rats, and dogs were successfully transplanted with minimal or no GVHD, across both major and minor histocompatibility barriers [12,13]. In the late 1970s, the development of monoclonal antibody technology helped to advance efforts to eliminate T cells from the donor graft and markedly decrease the incidence of GVHD in animal models [14,15].

T-cell dose and GVHD

Bone marrow used for human transplantation contains approximately $1–2 \times 10^{10}$ nucleated cells, of which up to 10–20% ($\sim 10^9$ cells) are mature lymphocytes. An average patient transplanted with unmodified bone marrow would thus receive a T-cell dose on the order of $1–4 \times 10^7$ cells/kg recipient body weight. Initially, it was not known what degree of TCD would be necessary to prevent GVHD, as immunofluorescence and erythrocyte (E) rosette assays for quantifying T-lymphocytes were not sufficiently sensitive to evaluate marrow that had been manipulated with antibodies. Limiting dilution assays suggested that at least a 2-log depletion of T cells to $1–3 \times 10^5$ cells/kg is necessary to significantly reduce GVHD in the HLA-identical related donor marrow transplant setting without exogenous immune suppression [16,17]. The target for ex vivo TCD studies is a T-cell inoculum below $0.5–1.0 \times 10^5$ cells/kg recipient body weight for HLA-matched related grafts. The extent of TCD needed to prevent GVHD likely depends not only on T-cell dose or log reduction, but also on other factors including donor source, type of graft, degree of major and minor HLA disparity, and

polymorphisms in immune response genes present in donor and recipient pairs. For example, granulocyte colony-stimulating factor (G-CSF)-mobilized blood hematopoietic cell products contain approximately 10-fold more T cells than unstimulated bone marrow grafts. Therefore, methods removing only 2 logs of T cells would likely be insufficient for GVHD prevention. CD34$^+$ selection of peripheral blood progenitor cells (PBPCs) with a 3–4 log reduction in CD3$^+$ count below 1×10^5 cells/kg is associated with lower rates of GVHD in matched sibling transplantation [18]. The T-cell threshold for patients receiving unrelated or haplotype mismatched hematopoietic cell products is likely at least 1 log lower.

T-cell number must also be considered in the context of the hematopoietic stem-cell progenitor dose, since the CD34$^+$ count may be also an important determinant of engraftment, GVHD, and survival after PBPC HCT [19,20]. The number of CD34$^+$ cells infused may have a greater impact in patients undergoing TCD transplants than those receiving conventional procedures. A report on 141 patients receiving mobilized PBPCs demonstrated that a higher number of CD34$^+$ cells infused was associated with lower non-relapse mortality (NRM), improved OS, and improved progression-free survival (PFS) after TCD, but not T-cell-replete, transplants [21].

Specificity of TCD

TCD techniques may vary not only in the extent of T-cell removal, but also in the selectivity of depletion. Some strategies remove all lymphoid and accessory cell fractions, including natural killer (NK) cells, B cells, and dendritic cells. These other cellular elements may play an important role in immune surveillance, engraftment, and elimination of residual disease post-transplantation. Other approaches have exclusively removed T cells, while still others have focused on specific phenotypically defined T-cell subsets. Studies have attempted to target donor T-lymphocytes expressing activation antigens after in vitro exposure to recipient antigen-presenting cells in order to eliminate only those cells likely to cause GVHD.

In 2000, a retrospective analysis of alternative donor bone marrow transplantation (BMT) at the Center for International *Blood* and Marrow Transplant Research (CIBMTR) compared negative selection TCD techniques with "narrow" and "broad" spectra of reactivity [22]. Examples of "narrow" specificity techniques included antibodies targeting mature T cells only, such as anti-T-cell receptor (TCR), anti-CD6, or anti-CD5, or T cells with specific functional roles, such as anti-CD8. Broad-specificity techniques include antibodies such as alemtuzumab (anti-CD52), multiple antibody combinations, and physical separation techniques such as lectin agglutination. Patients who received T-cell-depleted marrow using narrow-specificity antibodies had a superior 5-year leukemia-free survival to those receiving broad-specificity depletion, owing to a combination of increased relapse, graft failure, and transplant-related mortality in the broad-specificity TCD cohort [22]. Unfortunately, after over 30 years of research, it still is uncertain what anatomic T-cell subset mediates GVHD in humans and if that subset might vary between donor–patient pairs as a consequence of Class I or II presentation of different minor histocompatibility antigens driving the GVHD reaction. Selective CD8$^+$ TCD had attracted particular interest because preclinical data suggested CD8$^+$ T cells preferentially mediate GVHD. Early recovery of CD8$^+$ T cells after transplantation has been associated with subsequent development of GVHD [23]. Initial trials in HLA-identical sibling BMT in the early 1990s suggested that CD8$^+$ depletion with post-transplant cyclosporine alone could reduce the incidence and severity of GVHD without compromising the graft-versus-leukemia (GVL) effect [24]. However, results of CD8$^+$ depletion of mobilized PBPCs achieving a 2-log reduction have been disappointing, particularly if unrelated donors are used [25]. Nonetheless, CD8$^+$ TCD of donor lymphocyte infusions has been used successfully after TCD-HCT as a prophylactic and therapeutic strategy for disease relapse and for falling donor T-cell chimerism [26,27]. In these uncontrolled studies, low relapse rates were noted in the absence of significant GVHD.

Ex vivo negative selection TCD

Early studies of TCD using murine monoclonal antibodies alone reported acute GVHD rates of approximately 50% in HLA-identical sibling BMT recipients [28]. These results suggested that opsonization of T-lymphocytes alone might be insufficient to prevent acute GVHD in humans, and that additional lymphocyte lysis, facilitated by addition of complement to the antibody, was necessary. In the 1980s and early 1990s, phase II trials of ex vivo negative selection TCD with monoclonal antibodies plus complement or immunotoxins, which removed 2–3 logs of T-lymphocytes, decreased the incidence of GVHD to 10–20% after matched sibling BMT even in the absence of immune suppression post-transplantation [29–31]. Addition of anti-CD52 antibody directly to the hematopoietic cell product as it is being infused (alemtuzumab "in the bag") also resulted in a low incidence of grade II–IV acute GVHD in recipients of both bone marrow and mobilized peripheral blood cells [32]. A low frequency of acute GVHD was also noted with ex vivo physical separation techniques, such as soybean lectin agglutination/elutriation and counterflow centrifugal elutriation [17,32,33].

When unrelated donor transplants came into widespread use in the 1990s, there was considerable enthusiasm for applying this technology to this setting in light of the increased incidence and severity of acute GVHD. In a report from the National Marrow Donor Program (NMDP) in 1993, the use of TCD was the most significant factor predicting freedom from severe (grade III–IV) acute GVHD [34]. A subsequent analysis at the CIBMTR involving 1868 leukemia patients receiving marrow transplants from donors other than HLA-identical siblings revealed that the grade II–IV acute GVHD incidence was 34–38% for the TCD groups compared with 57% for the non-TCD cohort ($p < 0.0001$) [22]. While TCD did appear to reduce acute GVHD in unrelated marrow recipients, rates were not as low as those observed in the matched related donor setting. It is possible that in these early studies, unrecognized HLA disparities due to less sophisticated typing techniques contributed to higher rates of GVHD in the unrelated marrow recipients.

Despite over three decades of ex vivo TCD studies, only one large prospective randomized trial has been performed. This study, reported by Wagner et al. in 2005, included 410 recipients of HLA-identical unrelated bone marrow (Table 82.2). Patients were randomized to receive either T-cell-depleted bone marrow (by the monoclonal antibody $T_{10}B_9$ or elutriation) with post-transplant cyclosporine alone versus T-replete bone marrow with post-transplant cyclosporine and methotrexate as GVHD prophylaxis [6]. Both groups received cyclophosphamide and total body irradiation (TBI) for conditioning. Patients in the TCD arm received additional treatment to promote engraftment: ATG in the elutriation group and cytarabine in the $T_{10}B_9$ antibody group. The mean T-cell dose infused for the TCD was 1 log lower than that in the non-TCD arm. There was no difference in incidence of primary graft failure in the two groups. The incidence of grade II–IV acute GVHD was significantly lower in the TCD arm than the non-TCD arm (39% vs. 63%, $p < 0.0001$), and the cumulative rates of grade III–IV acute GVHD were 18% vs. 37%, respectively ($p < 0.0001$). Regimen-related toxicity was lower in the TCD arm. There was no difference in relapse rates in patients with acute leukemia although patients with chronic myelogenous leukemia (CML) were more than twice as likely to relapse if they received TCD bone marrow. Viral infection rates, particularly from cytomegalovirus (CMV) and other herpesviruses, were higher in the TCD group. Disease-free survival (DFS) and OS at 3 years were similar in the TCD and non-TCD arms. It is uncertain whether this trial represented a true test of the potential impact of TCD as the methods utilized only removed 1–2 logs of T cells. In addition, the inclusion of additional agents to promote engraftment and the use of cyclosporine for GVHD prophylaxis in the TCD arms cloud interpretation of the results.

Most early studies of ex vivo T-cell-depleted BMT concentrated on acute GVHD. As the devastating long-term consequences of chronic GVHD became more widely recognized, attention turned towards the impact of TCD on this late effect. The 1993 retrospective analysis from the NMDP had suggested that TCD reduced the risk of chronic GVHD after unrelated BMT [34]. However, the large prospective multicenter randomized trial of unrelated donor BMT described above failed to demonstrate any difference in the incidence and time to development of chronic GVHD between patients receiving cyclosporine plus TCD versus standard cyclosporine/methotrexate [6]. It is possible that the 1-log reduction in T cells achieved by the methods used in this study was insufficient to protect against chronic GVHD. Indeed, the retrospective study at the CIBMTR in 2000 examining the effect of broad and narrow specificity TCD demonstrated no protection by narrow antibody TCD against chronic GVHD despite a reduction in acute GVHD whereas exhaustive TCD with broad-based approaches did reduce chronic GVHD [22].

Ex vivo positive selection TCD

The increasing utilization of peripheral blood HCT and its attendant increase in chronic GVHD [35] make TCD a particularly attractive modality in this setting. Around the time when the use of mobilized PBPCs eclipsed bone marrow as the more common graft source for allogeneic HCT in adults, there also occurred a shift in the techniques employed for ex vivo TCD. Regulatory and commercial hurdles curtailed the use of negative selection strategies, replaced in large part by ex vivo $CD34^+$ positive selection technology. Initial studies of HLA-identical sibling PBPC HCT using ex vivo $CD34^+$ positive selection initially reported a wide variation in acute GVHD incidence from 8% to 100% [36,37]. This variability was likely influenced by factors such as the number of $CD3^+$ cells infused, immune suppressive agents given after transplant, and the manner in which these devices were used. A study comparing three devices (CEPRATE, Isolex 300i, and CliniMACS) found no apparent differences in the allograft composition or clinical outcomes, although ease of processing did differ [38]. Initial studies using CD34 selection columns showed that a 2-log reduction in T cells from matched related donor PBPCs was insufficient to control GVHD despite the use of cyclosporine ± methotrexate as post-transplant immune suppression [36]. This was perhaps not surprising given the larger number of T cells in peripheral blood compared with bone marrow. However, subsequent studies demonstrated that when the T-cell content in the sibling PBPC graft was reduced by

3.0–3.5 logs, grade II–IV acute GVHD was only 10% [37]. Single institution studies at the Memorial Sloan Kettering Cancer Center have demonstrated very low rates of acute and chronic GVHD in a variety of disease settings when CD34 selection was combined with sheep erythrocyte resetting to deplete residual donor T cells [39].

One of the challenges of ex vivo TCD has been reproducibility at different sites. Historically, most centers developed their own technologies, and multicenter trials were uncommon. However, in 2005, the *Blood* and Marrow Transplantation Clinical Trials Network (BMT CTN) launched a multicenter trial of $CD34^+$ selection as the sole form of GVHD prophylaxis in patients receiving matched related donor transplantation for acute myeloid leukemia (AML) after TBI-based conditioning [40]. AML was chosen as the target indication as the prospective randomized trial in unrelated BMT reported by Wagner et al. demonstrated that TCD was not associated with an increased rate of relapse in patients with AML [6]. In this BMT CTN trial, a total of 44 patients with AML were transplanted at eight centers. All patients engrafted promptly. The incidences of grade II–IV and grade III–IV acute GVHD were 22.7% and 4.8%, respectively, while the incidence of extensive chronic GVHD was 6.8% at 24 months. Differences in processing outcomes between centers were minimal. All products infused met the prespecified goal of less than 1×10^5 CD3 cells/kg recipient body weight. All patients received $>2 \times 10^7$ $CD34^+$ cells/kg and 82% achieved the goal of 5×10^7 $CD34^+$ cells/kg. $CD34^+$ cell recovery was 66.1% and was inversely associated with the starting number of $CD34^+$ cells. The median purity of the CD34-enriched fraction was 96.7% with monocytes and B cells the most common impurity [41]. These results were compared with outcomes of 84 AML patients receiving T-replete matched related donor grafts and pharmacologic immunosuppressive therapy (IST) treated in contemporaneous trials sponsored by the CTN [42]. The 100-day rates of grade II–IV acute GVHD were 23% and 39% with TCD and IST grafts, respectively ($p = 0.07$). Two-year rates of chronic GVHD were lower with TCD grafts than IST (19% vs. 50%, $p < 0.001$). There were no differences in rates of graft rejection or leukemia relapse in the TCD and IST cohorts, Treatment-related mortality and disease-free and OS rates were also similar in the two groups. At 1 year, 54% and 12% of patients were still on immune suppression in the IST and TCD cohorts, respectively. TCD led to a higher GVHD-free survival at 2 years compared with IST (41% vs. 19%, $p = 0.006$). A retrospective study from the Memorial Sloan Kettering Cancer Center and the M.D. Anderson Cancer Center examined outcomes of transplants for patients with AML in first remission at the two institutions, where TCD was utilized at one center and conventional GVHD prophylaxis at the other. The incidences of grade II–IV acute GVHD and chronic GVHD were significantly lower in the TCD graft group (5% vs. 18% and 13% vs. 53%). Three-year relapse-free survival (RFS) and OS rates were comparable in recipients of TCD and unmodified grafts [43]. These comparative analyses emphasize the need for a prospective randomized trial to assess the impact of ex vivo TCD on chronic GVHD free survival.

Haploidentical donor TCD transplantation

Overcoming major HLA barriers to permit transplantation of mismatched grafts remains a major goal of allogeneic transplantation. It has long been hoped that TCD could make that goal a reality. Although early studies of TCD in HLA-mismatched related BMTs were plagued by high incidences of graft failure and GVHD, later series have demonstrated better results. Grade II–IV GVHD incidence has ranged from 13% to 40% in recipients of HLA-mismatched BMT after TCD using monoclonal antibody and complement alone or in conjunction with steroids, cyclosporine, and ATG [44,45]. Unfortunately, the overall outcome was compromised by increases in graft failure, infection, and relapse.

Improved engraftment of T-cell-depleted haploidentical hematopoietic cells has been achieved through infusion of high ("mega") doses of mobilized peripheral blood cells depleted of T cells after $CD34^+$ selection [46,47]. Immunologic analysis of these haploidentical extensively T-cell-depleted transplants led to an appreciation of the role of NK cells and killer-cell immunoglobulin-like receptors (KIRs) in allorecognition and GVHD [46,48]. In these studies, acute leukemia patients underwent haploidentical transplantation with an intensive high-dose conditioning regimen coupled with extensive TCD using sheep red blood cell (RBC) rosetting and CD34 selection of the PBPC product. No post-transplant immune suppression was given. Among 60 patients transplanted, only four cases of GVHD were observed. Notably, patients in this group whose donor–recipient HLA disparity predicted KIR mismatch and NK-cell alloreactivity in the graft-versus-host direction experienced no graft failure, acute GVHD, or myeloid leukemia relapse. High frequencies of alloreactive donor NK cells were detected in recipient blood post-transplant that could specifically lyse leukemia targets missing KIR ligands, and not control target cells that expressed the "self" KIR ligand. Specific KIR and HLA genotypes associated with NK activation have also been demonstrated to have prognostic importance in the setting of HLA-identical T-cell-depleted transplantation for AML [49]. A European Group for *Blood* and Marrow Transplantation (EBMT) survey of 173 adults undergoing haploidentical HCT after exhaustive TCD demonstrated similar results [50]. The most frequently encountered limitation of this approach has been immune incompetence and increased risk of fatal infections. Attempts to address this stumbling block have focused infusions of conventional donor T cells either alone, after photodepletion, or in conjunction with regulatory T cells, with promising results reported in single-institution studies [51,52].

In vivo anti-T-cell antibody TCD

Whereas ex vivo methods of TCD may allow engineering of a graft with a precise T-cell dose, in vivo administration of anti-T-cell antibodies yields a level of T-cell reduction that is much less predictable, owing to the variable half-lives of these antibody preparations, the doses of antibodies used, the administration schedule, and the number of T cells contained in the donor graft. There are currently four products in widespread use in different geographic locations around the world. Three of these are polyclonal anti-T-cell antibody preparations that are considered antithymocyte globulins (ATGs). These products are all different and should be evaluated individually. Atgam is produced from horses inoculated with human thymocytes. Thymoglobulin is also directed against human thymocytes but is raised in rabbits. ATG-Fresenius, also rabbit derived, is actually not an antithymocyte preparation at all but is directed against a Jurkat T-cell leukemia line. Consequently, the antigens targeted and cells eliminated will vary depending on antibody preparation used [53]. Alemtuzumab is a monoclonal antibody directed against CD52, which is broadly expressed on T cells and also other cellular elements including B cells and dendritic cells.

Most comparative studies on the efficacy of adding in vivo TCD to conventional pharmacologic GVHD prophylaxis have been retrospective. In a matched pair analysis, Russell et al. found that at a Thymoglobulin dose of 4.5 mg/kg, acute and chronic GVHD rates were significantly lower compared with immunosuppressive therapy alone in matched related graft recipients following high-dose busulfan/fludarabine-based conditioning. Non-relapse mortality was also lower. Despite a higher relapse rate in the ATG cohort, OS was superior (66% vs. 50%, $p = 0.046$) in ATG recipients [54]. This report is the only retrospective or prospective study that has shown a survival advantage for in vivo TCD. Bredeson et al. at the CIBMTR conducted a matched-pair analysis of Thymoglobulin use in patients conditioned with high-dose busulfan plus cyclophosphamide. Again, ATG was associated with lower acute GVHD rates, but not chronic GVHD rates. Non-relapse mortality was lower but relapse was higher in the ATG cohort, resulting in no difference in disease-free survival [55]. Similar patterns have been noted in single-institution series utilizing alemtuzumab, lower GVHD rates, but higher infection and relapse rates with no difference in OS [56]. The CIBMTR compared pediatric acute lymphoblastic leukemia (ALL) patients undergoing myeloablative HCT receiving ATG preparations ($n = 191$), alemtuzumab ($n = 131$), or no in vivo TCD ($n = 392$). Doses and origin of ATG preparations were not specified. Both ATGs as a class and alemtuzumab were associated with lower rates of acute and chronic GVHD. Lower GVHD rates did not affect relapse incidence, nor was there any effect on NRM. Consequently, in vivo TCD did not improve event-free survival or OS [57]. Mohty et al. reported a retrospective experience of myeloablative HCT with or without Thymoglobulin in adult patients. ATG recipients did not have a statistically significant reduction of acute GVHD although there was a dramatic decrease in chronic GVHD [58]. Again, there was no impact on relapse, NRM, leukemia-free survival (LFS), or OS.

There is substantial evidence that the dose of in vivo T-cell antibodies influences both GVHD incidence and immune reconstitution. Retrospective French series in matched related donors examining doses of 2.5, 5.0, and 7.5–10 mg/kg Thymoglobulin demonstrated that higher doses were associated with lower rates of acute and chronic GVHD, but that did not translate into an improvement in LFS or OS [59,60]. Fewer comparative studies have been performed with other ATG preparations, but one study of ATG-Fresenius suggested that equivalent GVHD control can be achieved with lower doses than in standard use (30 vs. 60 mg/kg) with a suggestion of lower NRM [61].

ATG levels have been measured after infusion in an attempt to correlate these levels with clinical outcomes. Remberger and Sundberg studied rabbit IgG levels on days 0, 1, and 7 after unrelated donor HCT and found a correlation between high levels and protection from acute GVHD [62]. Podgorny et al. examined ATG levels on days 7 and 28 after transplant in patients who had received 4.5 mg/kg of Thymoglobulin. Low levels at those times correlated with increased acute and chronic GVHD whereas high levels were associated with the development of post-transplant lymphoproliferative disorder (PTLD). ATG levels, however, did not impact relapse or OS [63]. After umbilical cord blood transplantation, low serum levels of ATG (Thymoglobulin) on day 11 were associated with higher rates of grade III–IV acute GVHD and higher NRM, but a lower incidence of relapse [64]. Hoegh-Petersen et al. went one step further, examining day 7 serum levels of ATG antibodies specific for particular lymphoid subsets in 120 patients who had received 4.5 mg/kg of Thymoglobulin. They found that high levels of antibodies with specificities for conventional T and B cells were associated with lower acute GVHD and higher viral infection rates, without relation to relapse. Of interest, high specificities to both regulatory T (Treg) cells and invariant natural killer T (NK-T) cells were linked to lower relapse rates [65].

There may be other factors in addition to the actual ATG dose and number of T cells in the graft that affect ATG dose levels. Studies of solid organ transplant recipients have identified that the presence of antibodies to rabbit-derived globulin in the serum accelerates clearance and results in lower serum level of ATG. One group reported that 20 of 72 pediatric patients who had received ATG developed anti-ATG antibodies. In those who developed IgG (as opposed to IgM) anti-ATG antibodies before day 22, rapid clearance of ATG was observed, as was faster T-cell recovery and a higher rate of acute GVHD [66].

Unfortunately, there are only a limited number of prospective randomized controlled trials available to assess intravenous TCD. Kumar et al. reviewed seven such trials enrolling 733 patients randomized to receive ATG. Pooled results showed no difference in NRM or OS with use of ATG. There was a significant benefit for prevention of grade III–IV acute GVHD. Insufficient data were available to assess chronic GVHD in this review [67]. In two of these randomized trials, Bacigalupo et al. compared cyclosporine/methotrexate with cyclosporine plus Thymoglobulin (15 mg/kg in one study, 7.5 mg/kg in the other) in recipients of matched unrelated donor myeloablative BMT. Only the higher dose of ATG was associated with a significant reduction in grade III–IV acute GVHD. However, this reduction in severe acute GVHD did not improve outcomes because 30% of the patients in the high-dose ATG arm died of severe infections. OS was not affected by the use of either dose of ATG [68]. Data from these randomized ATG trials suggested a reduction in chronic GVHD for those receiving ATG with a reduction in long-term pulmonary complications and late deaths [69].

The largest prospective randomized trial of in vivo TCD was conducted in Europe and compared patients randomized to conventional pharmacologic GVHD prophylaxis alone with those randomized to immune suppression plus ATG-Fresenius at a dose of 20 mg/kg administered on days –3, –2, –1 (60 mg/kg total). A total of 250 patients were registered. Finke et al. reported lower grade II–IV acute GVHD in the ATG-Fresenius group (33% vs. 51%, $p = 0.011$) and lower grade III–IV rates (11.7% vs. 24.5%, $p = 0.054$). The most striking difference was in extensive chronic GVHD incidence (12.2% vs. 42.6%, $p < 0.0001$). Relapse rates, NRM, DFS, and OS were not significantly different in the two groups [70]. Socié et al. reported the extended follow-up of these patients and found that immune suppression-free survival was markedly superior for the ATG-Fresenius group [71]. As of 2013, two additional large prospective randomized trials are under way, one assessing Thymoglobulin in Canada and a blinded trial testing ATG-Fresenius in myeloablative transplantation in the United States. Results of these trials will be extremely valuable in establishing the role of these agents in recipients of full-intensity conditioning. If these studies demonstrate lower GVHD rates despite no OS advantage, they still might represent an important advance, as Yu et al. demonstrated in a comparative series that ATG administration was associated not only with lower GVHD rates, but also improved quality of life parameters [72].

In vivo TCD and reduced-intensity conditioning HCT

Over the past decade, there has been a dramatic increase in the use of reduced-intensity conditioning (RIC) allogeneic HCT. The primary antitumor activity in RIC procedures stems not from the cytotoxic effects of low-dose chemotherapy, but from the alloimmune effect of the donor cells. Hence there might appear to be little rationale for TCD in RIC HCT if TCD substantially blunted the GVL effect, thereby defeating the purpose of the transplant itself. Furthermore, RIC preparative regimens might not be sufficiently immune suppressive to support and sustain the engraftment of T-cell-depleted hematopoietic cells or marrow. Nonetheless, both ATG preparations and alemtuzumab have been used to achieve simultaneous depletion of donor and host T cells to ensure engraftment and reduce in GVHD in RIC HCT. As with high-dose transplantation, these antibodies lead to delayed immune reconstitution and a higher incidence of disease relapse and virus infections, especially from CMV and adenovirus [73–75].

There is no consensus on which antibody preparation yields the best results. In a comparative analysis of two prospective studies using either alemtuzumab/cyclosporine or cyclosporine/methotrexate as GVHD prophylaxis after RIC, there was a significantly lower incidence of acute and chronic GVHD in the alemtuzumab patients, but a higher incidence of CMV reactivation and disease relapse/progression [73]. However, long-term disease and OS status were similar in the two cohorts when responses were considered after donor lymphocyte infusion (DLI) in the patients in the alemtuzumab arm. These data and others suggest that TCD can be used to induce a state of mixed chimerism with minimal GVHD, and provide a platform for additional adoptive immunotherapy interventions such as DLI or vaccinations to bolster immune function and GVL [27,76,77]. Ex vivo TCD has also been studied in RIC HCT. $CD34^+$ selection of donor PBPCs after RIC led to a low rate of GVHD [78]. However, both engraftment and disease relapse have been problems in the absence of additional DLI.

Unfortunately, there has yet to be a prospective randomized trial evaluating the consequence of in vivo anti-T-cell antibody administration in RIC HCT. It is critical to determine whether immune modulation with anti-T-cell antibody infusion abrogates the therapeutic benefits of transplantation. The CIBMTR examined 1676 adults undergoing RIC-related ($n = 792$) and -unrelated ($n = 884$) HCT for hematologic malignancies [79]. Outcomes after in vivo TCD ($n = 584$ ATG, $n = 213$ alemtuzumab) were compared with T-cell-replete ($n = 879$) transplantation. Engraftment was not aided by in vivo TCD; in fact, it was slightly inferior. Grade II–IV acute GVHD was lower with alemtuzumab than ATG or T-cell-replete regimens (19% vs. 38% vs. 40%, $p < 0.0001$) and chronic GVHD, and lower with alemtuzumab and ATG regimens than T-cell-replete approaches (24% vs. 40% vs. 52%, $p < 0.0001$). However, relapse was more frequent with alemtuzumab and ATG than T-cell-replete regimens (49%, 51%, and 38%, respectively, $p < 0.001$). DFS was lower with both alemtuzumab and ATG than T-cell-replete regimens (30%, 25%, and 39%, respectively, $p < 0.001$). Corresponding probabilities of OS were 50%, 38%, and 46% ($p = 0.008$). The EBMT conducted a similar analysis in 1859 AML patients undergoing RIC HCT [80]. In vivo TCD with ATG or alemtuzumab was successful at preventing extensive chronic GVHD ($p < 0.001$), but without improving OS for ATG and even with worsening OS for alemtuzumab (hazard ratio 0.65, $p = 0.001$). These collective data suggest adopting a cautious approach to in vivo TCD with RIC regimens and emphasize the need for randomized controlled trials in the RIC setting.

Organ Dysfunction and TCD

In single-institution TCD series, low rates of hepatic, renal, and pulmonary complications have been reported [81–83]. In an analysis of 199 allogeneic transplants, the incidence of severe pulmonary complications was 8% among those who received CD6 TCD as the sole form of GVHD prophylaxis, but 33% among those who received cyclosporine and methotrexate [83]. The protective effect of TCD against pulmonary complications was independent of acute GVHD. The incidence of hepatic sinusoidal obstructive syndrome (SOS), has been reported to be fairly low after TCD BMT [81,82]. This reduction in hepatotoxicity may be due to the fact that the TCD patients are spared from injurious effects of methotrexate and/or cyclosporine/tacrolimus. Alternatively, decreases in alloreactivity may lead to lower levels of circulating cytokines that could damage hepatic endothelium. In the 410 patient prospective randomized study reported by Wagner et al., recipients of T-cell-depleted marrow experienced less regimen-related toxicity within the first 28 days of transplant, including stomatitis ($p < 0.0001$), hepatic ($p = 0.0003$), pulmonary ($p = 0.012$), and central nervous system complications ($p = 0.024$) [6].

Engraftment and TCD

Graft failure or rejection has been reported to occur more frequently in patients receiving TCD bone marrow than in recipients of T-cell-replete grafts. Whereas graft failure usually occurs in 1% or less of patients with leukemia receiving HLA-identical products, studies from the 1980s and early 1990s reported graft failure rates of 3–40% depending on the methodology used. Registry analysis from the CIBMTR in the era identified a significantly increased risk for graft failure compared with unmanipulated BMT (relative risk 9.29, $p < 0.0001$) [34].

Graft failure after TCD HCT may occur in two patterns: (1) failure of initial engraftment or graft rejection within 2 weeks of HCT, and (2) delayed graft failure which can occur months following transplant. Early graft failure after TCD transplantation likely represents primary immunologic rejection of donor hematopoietic elements by host lymphoid cells that have survived the conditioning regimen. Host T-lymphocytes with donor-specific activity have been isolated from the blood of patients at the time of graft rejection [84,85]. It is likely that TCD removes cells that are important for promoting engraftment. However, it remains uncertain what roles specific donor cells play in establishing and maintaining a graft in human transplantation. Graft failure has been much less commonly observed in recent studies of TCD-mobilized peripheral blood HCT. In a 2007 report, all 52 patients transplanted with $CD34^+$-selected TCD-matched sibling-mobilized PBPCs engrafted after conditioning with fractionated TBI, *N*-triethylenethiophosphoramide (thioTEPA), and fludarabine without ATG, despite only receiving a median of 0.99×10^3 cells/kg [86]. Other series from the past decade have likewise reported low graft failure rates [39,40].

The mechanism behind late graft failure remains unknown. Unlike primary rejection, donor-specific host T-lymphocytes have not been isolated from the blood of recipients at the time of late graft failure. Since mixed hematopoietic and lymphoid chimerism is common after TCD transplantation, late graft rejection may result when this state of immune tolerance is broken by some event. Even in patients in whom hematopoietic recovery is observed, there is an increased frequency of mixed hematopoietic chimerism [87]. This has been particularly noted in the T-cell compartment. Viral infections with CMV or human herpesvirus 6 (HHV6) may also contribute to late graft failure after HCT [88,89].

Attempts to thwart immunologic rejection after HCT have included increasing host immune suppression, intensification of the conditioning regimen to create space or additional immune suppressive agents after transplantation [32,44,90]. It is not clear how intensive conditioning must be to achieve hematopoietic recovery after TCD transplantation. Successful engraftment of haploidentical family donor PBPCs using an RIC regimen plus alemtuzumab has been reported with a 16% incidence of grade II–IV acute GVHD [91]. Other approaches have included narrowing the spectrum of TCD, infusion of increasing doses of CD34$^+$ cells in the graft, and administration of donor lymphocytes after transplantation. There are no randomized data available to support the use of any of these interventions.

Immune reconstitution and infectious complications after TCD HCT

Immune reconstitution is delayed after ex vivo TCD [92–95]. In general, total lymphocyte counts are lower in recipients of TCD grafts. Prolonged inversion of CD4$^+$/CD8$^+$ ratios are observed with delays in CD4$^+$ T-cell recovery. The number of T cells with memory phenotypes is decreased. Delays in functional recovery of T cells after TCD HCT have also been described. Proliferative responses of PBMCs to mitogenic stimuli are impaired far longer after TCD transplants than after conventional procedures [92]. T-lymphocytes from recipients of TCD BMT have restricted variability in their T-cell receptor repertoires, limiting the breadth of potential cellular responses [93]. The capacity to generate new T cells is impaired after TCD, as noted by decreased numbers of thymic emigrants measured by T-cell receptor excision circle (TREC) analysis [94,95]. Deep sequencing techniques have demonstrated that recovery of T-cell receptor diversity is particularly delayed in CD8$^+$ cells after TCD HCT, even more so than in T cells following umbilical cord blood HCT [96]. Comparative studies on immune reconstitution after in vivo TCD with ATG administration have demonstrated high levels associated with slower T-cell but more rapid B- and NK-cell recovery [97].

Delayed immune reconstitution and loss of TCR repertoire diversity may place TCD HCT recipients at increased risk for opportunistic infections. CMV reactivation and adenovirus infections occur more frequently after TCD transplants and in recipients of in vivo anti-T-cell antibodies, particularly alemtuzumab [73–75,98]. Partial TCD may not abrogate transfer of anti-CMV T-cell immunity although protection against CMV appears lost with more extensive depletion [99,100]. In a large randomized study of ex vivo TCD in unrelated BMT, the overall rate of fatal infections did not differ between the TCD and non-TCD arms. Bacterial infections were not increased. However, higher incidences of severe CMV (28% vs. 17%, $p = 0.02$) and life-threatening *Aspergillus* (16% vs. 7%, $p = 0.01$) infections were observed in the patients receiving TCD [6,101].

A number of studies have demonstrated a higher probability of Epstein–Barr virus (EBV) reactivation in recipients of TCD grafts [3]. Recipients of TCD transplants using HLA-mismatched or unrelated donor marrow appear to be at particularly high risk, as are patients with severe GVHD and those treated with specific anti-T-cell monoclonal antibodies. Recipients of cord blood transplantation are also at high risk for EBV–PTLD, especially if they are conditioned with a reduced-intensity regimen that includes ATG [102]. Rituximab has been utilized as therapy for PTLD [103] and in a preemptive mode in the setting of rising EBV viral loads in the absence of documented disease [104]. Donor lymphocyte infusions have been successful in treating PTLD but may induce GVHD [105]. EBV-specific cytotoxic T cells have been demonstrated to lead to regression of PTLD with only limited GVHD [106]. The production of virus-specific T-lymphocytes with the capacity to recognize CMV, EBV, and adenovirus but without alloreactive potential is being studied in both therapeutic and prophylactic settings [107,108]. Other strategies to accelerate recovery of T-cell immunity after TCD HCT include attempts to improve thymic function through administration of interleukin (IL)-7 and luteinizing hormone-releasing hormone (LHRH) antagonists [109,110].

Disease relapse and TCD

The increased risk of disease relapse after TCD BMT was initially recognized in patients with CML. In patients receiving matched sibling BMT for first chronic-phase CML, the risk of relapse with TCD has been estimated to be 5–6-fold higher than in conventional transplantation [4,5]. The incremental risk of relapse is less apparent after TCD transplantation using matched unrelated marrow [111]. A study at the EBMT demonstrated that in patients with CML who received unrelated donor BMT, TCD was not associated with a higher incidence of relapse in the multivariate analysis [112]. However, in the large multi-center randomized trial of TCD reported by Wagner et al., the 3-year relapse incidence was higher in the TCD patients transplanted for CML (20% vs. 7%, $p = 0.017$) [6].

The increased incidence of CML relapse after TCD HCT has been linked, at least in part, to the reduction in GVHD. It is well established that allogeneic HCT is superior to autologous or syngeneic transplants in CML because donor T cells can mediate alloimmune responses, and patients who develop clinically significant GVHD have a better LFS after HCT [113]. Direct evidence of the importance of donor T cells in the GVL effect have been derived from DLI studies for patients with CML who have relapsed after allogeneic BMT, where complete remission rates of 70–80% were achieved [114,115]. The diseases for which DLI appears efficacious are the same as those in which TCD has been linked to increased relapse rates. These include, in addition to CML, both multiple myeloma and chronic lymphocytic leukemia. The risk of leukemia relapse may also vary depending on the extent and specificity of TCD employed. “Narrow-specificity” antibodies appear to be associated with a lower relapse rate than “broad-specificity” TCD methods. The 5-year probability of leukemia relapse was 28% for recipients of narrow-specificity TCD BMT versus 51% for recipients T-depleted by other techniques ($p < 0.001$) [22]. The 5-year relapse rate for recipients of “narrow-specificity” TCD was similar to that observed in patients who received unmanipulated BMT. Risks factors for relapse after TCD HCT may be linked to genetic polymorphisms in the donor CTLA4 genotype and the capacity to generate and sustain a GVL response [116].

In contrast to CML, TCD appears to have a less significant effect on the relapse rates of patients transplanted for acute leukemia [117,118]. In two separate randomized trials comparing TCD with methotrexate and cyclosporine as GVHD prophylaxis for patients undergoing HLA-matched related or unrelated BMT, a higher relapse rate was observed after TCD BMT only in patients with CML, not in patients with acute leukemia [6,119]. In addition, in the comparative study of CD34$^+$ TCD reported by the BMT CTN in AML patients and in the randomized ATG-Fresenius trial including AML, myelodysplastic syndrome, and ALL, both after myeloablative conditioning, there was no increase in relapse rate with either ex vivo or in vivo TCD [42,70,71]. These trials excluded patients with advanced disease, hence this observation should not be extrapolated to all patients. Nor should it be extended to patients receiving RIC conditioning, as the retrospective analyses of the CIBMTR and EBMT clearly show a higher relapse rate for both ATG and alemtuzumab in this setting [79,80].

Efforts aimed at reducing leukemia relapse after TCD have focused primarily on immune-based strategies to enhance GVL activity without compromising GVHD prevention. These approaches have included selective purging of T-lymphocyte subsets (e.g. $CD8^+$ T cells), prophylactic donor lymphocyte infusion, and induction of NK cell-mediated antitumor activity. Donor lymphocyte infusion or T-cell add-back strategies have been used in conjunction with TCD to restore GVL activity and prevent disease relapse. Prophylactic DLI strategies may be useful after TCD HCT using CD34 selection, ATG, or alemtuzumab, where the extensive depletion leads to profound and long-lasting impairment of immunity [69,75–78,120]. Unfortunately, GVHD is common after these infusions. Although the incidence of GVHD after prophylactic DLI is similar to that with conventional transplantation, a report suggests that chronic GVHD after T-cell add-back is associated with less mortality, but retains its protective effect on relapse [120]. Retrospective studies in patients with CML and multiple myeloma undergoing high-dose transplantation have suggested that TCD plus DLI is a reasonable alternative to conventional GVHD prophylaxis, and may in some circumstances be associated with superior outcome [121–123]. An update of the Spanish and British RIC experience in Hodgkin lymphoma suggested that with the addition of DLI, current DFS was superior for patients treated with cyclosporine/alemtuzumab than those receiving cyclosporine/methotrexate for GVHD prophylaxis, although again randomized data are lacking [124].

Novel approaches to graft manipulation

Novel strategies to limit the risk of GVHD associated with either hematopoietic cell or donor lymphocyte infusions are under investigation and include photoinactivation, anergy induction, and elimination of cells expressing activation antigens (e.g., CD25, CD69). These approaches usually involve a brief coincubation of donor cells with recipient-derived antigen-presenting cells. Theoretically, this approach would preferentially purge alloreactive lymphocytes responsible for GVHD, but retain "non-alloreactive" T cells that might improve post-transplant immune reconstitution against infectious pathogens [125]. If minor histocompatibility antigens responsible for GVH, but not GVL, can be routinely identified, then targeted depletion of those cells recognized those minor antigens could represent a major advance [126].

Herpes simplex thymidine kinase (HSV-TK) gene insertion into donor T cells represents another approach for controlling GVHD after allogeneic transplantation or DLI. These cells have been rendered susceptible to destruction after exposure to ganciclovir. Infusion of $HSV\text{-}TK^+$ T-lymphocytes with TCD marrow graft did not hamper engraftment, and resulted in stable establishment of circulating TK^+ cells in the recipient post-transplant [127]. HSV-TK gene insertion has also been studied in the DLI setting without compromise of antitumor activity [128]. In one study, a direct correlation between antitumor response with peak levels of TK^+ cells in circulation was seen. Moreover, circulating TK^+ cells could be disrupted by the administration of ganciclovir.

More recently, the recognition that certain T cells have regulatory function that can suppress graft-versus-host reactions may play a role in the design of future TCD strategies that spare these negative regulators [129,130]. $CD4^+CD25^+Foxp3^+$ regulatory T (Treg) cells have been identified as important mediators of self-tolerance, auto/alloimmunity, and immune reconstitution after HCT. Murine transplant models have demonstrated that Treg cells are potent suppressors of alloimmune responses, and can protect against GVHD [129,131]. Lower levels of Treg cells have been associated with development of acute and chronic GVHD [132,133]. Infusions of cultured Treg cells have been used to try to prevent GVHD after umbilical cord blood transplantation [134]. Early uncontrolled data suggest that infusion of freshly isolated Treg cells can prevent induction of GVHD by conventional T cells when administered around the time of transplantation [52]. In vivo expansion of Treg cells with low doses of recombinant IL-2 are being investigated in patients with established chronic GVHD based upon the observations from clinical trials that this cytokine preferentially expands Treg cells in cancer and transplant patients [135]. Low dose IL-2 has been used as a means to treat correct Treg cell deficiency in patients with established refractory chronic GVHD with promising results reported [136]. Results from trials combining adoptive Treg cell immunotherapy with IL-2 administration are under way.££

Conclusion

Although it is clear that TCD reduces the incidence of acute and chronic GVHD, there is as yet no definitive evidence that TCD improves OS after HCT. Nonetheless, many investigators remain optimistic that graft engineering and targeted T-cell antibodies will one day fulfill the promise of separating GVH and GVL. Current evidence suggests that in patients with acute leukemia undergoing myeloablative transplantation, in vivo and ex vivo TCD can do just that. However, that may not be true after RIC HCT. Further delineation of the cellular subsets that promote engraftment and control alloimmune, antitumor, and antiviral responses is needed to optimize graft engineering. It is critical that as promising ex vivo or in vivo TCD strategies are developed, they be definitively tested in prospective randomized trials.

CHAPTER 83

Manifestations and Treatment of Acute Graft-versus-Host Disease

Corey Cutler and Joseph H. Antin
Harvard Medical School, Dana Farber Cancer Institute, Boston, MA, USA

Background, definition, and incidence of acute graft-versus-host disease

The first description of graft-versus-host disease (GVHD) is ascribed to Barnes and Loutit in 1955, who reported on "secondary disease" in animals undergoing transplantation [1]. Since then, much of the pathophysiology of acute GVHD has been deciphered (reviewed in Chapter 13); however, much remains to be learned. A review of methods to prevent acute GVHD through pharmacologic and graft manipulation can be found in Chapters 81 and 82, and this chapter discusses the diagnosis and treatment of established acute GVHD.

The term acute GVHD traditionally described a distinctive syndrome of cutaneous, hepatic, and gastrointestinal (GI) inflammation developing within 100 days of allogeneic hematopoietic cell transplantation (HCT). The term chronic GVHD described a more pleiotropic syndrome that developed after day 100 (see Chapter 84). However, it is now recognized that acute GVHD can occur after day 100 and chronic GVHD may occur before then, and the syndromes are currently defined by their clinical features, rather than their timing in relation to transplantation. Late-onset acute GVHD predominantly occurs after reduced-intensity conditioning (RIC) regimen-based allogeneic transplantation [2] or in the context of rapid immunosuppressant tapering.

Incidence and staging

Table 83.1 presents the commonly used Consensus criteria for the staging and grading of acute GVHD [3,4]. A modification of grade II disease includes symptoms of nausea, anorexia, food intolerance, or vomiting confirmed to be enteric GVHD on upper intestinal biopsy [4,5]. The staging system proposed by the International Bone Marrow Transplant Registry (IBMTR) uses the same individual organ staging but modifies the overall grading scheme slightly (Table 83.2) [6]. Although both systems predict overall survival equally well, the Consensus system predicted earlier survival better in a comparison of 607 patients. The IBMTR index, however, was easier to use and was associated with less physician bias or error in stage assignment [7].

Depending on the prophylactic regimen used, clinically relevant grade II–IV acute GVHD occurs in 20–40% of patients transplanted from a matched sibling donor [8] and in 30 to >50% of recipients of unrelated donor grafts [9,10]. Severe acute GVHD (grade III–IV) occurs in up to 20% of recipients of related donors [8] and up to 35% of unrelated donors [9,10]. Reliable incidence figures for acute GVHD are limited by interobserver and intercenter variation. This variability largely derives from uncertainty in establishing grade II GVHD [11,12]. The median time to the diagnosis of acute GVHD varies with conditioning, with recipients of myeloablative conditioning being diagnosed at a median of 17 days from transplantation [13], in comparison with recipients of RIC transplantation being diagnosed at a median of 3 months [2], and is more commonly associated with the tapering of immunosuppressive agents.

Risk factors for acute GVHD

Human leukocyte antigen disparity

Human leukocyte antigen (HLA) disparity between the hematopoietic cell donor and recipient is the most powerful factor governing the severity and kinetics of acute GVHD. The incidence of acute GVHD is much increased with HLA-non-identical donors compared with HLA-identical donors [14].

Although traditionally the HLA class I antigens HLA-A and HLA-B and the class II antigen HLA-DRβ1 have been used for matching purposes, other HLA antigens, namely HLA-C, HLA-DQ, and HLA-DP, are also relevant in acute GVHD and transplantation outcomes [15–19]. In a large, retrospective National Marrow Donor Program (NMDP) study, Lee et al. demonstrated that both allelic and antigenic mismatches at any single locus, when compared with fully matched unrelated donor transplantation, were associated with excess acute GVHD; however, no differences between antigenic and allelic mismatches were noted overall [20]. When examined at individual HLA loci, mismatches at any given locus were associated with a relative risk increase of acute GVHD of approximately 1.6-fold, although not all comparisons were statistically significant owing to small sample sizes.

Although some studies have identified individual HLA antigens that are associated with increased rates of GVHD [21], these correlations have not been observed consistently [22,23]. It is likely that as further refinements to HLA-typing techniques are made, and an improved understanding of how individual disparities in HLA affect antigen presentation, recognition, and signal transduction is developed, the role of individual HLA disparities will become more evident.

Hematopoietic stem-cell source and graft composition

The source of allogeneic hematopoietic cells may also influence the development of GVHD. For more than two decades, experience was derived from bone marrow transplant (BMT) recipient cohorts

describing rates and risk factors for GVHD [21–23]. Recently, peripheral blood progenitor cells (PBPCs) have become the most utilized source of hematopoietic cells for both related and unrelated donor transplantation [24]. Initial phase 2 studies of matched, related donor PBPC transplantation demonstrated an increased incidence of acute GVHD [25–28], and multiple randomized, controlled trials have compared GVHD outcomes between matched sibling BMT and PBPC transplantation [29–36]. In the largest randomized trial involving 350 patients enrolled between 1995 and 1999, grade II–IV and grade III–IV acute GVHD were significantly higher in the PBPC group (52% vs. 39%, p = 0.014, and 28% vs. 16%, p = 0.01, respectively). In this trial, however, an abbreviated three-dose course of methotrexate was used in both arms as GVHD prophylaxis [35]. A randomized trial involving the Seattle, City of Hope, and Stanford groups demonstrated a non-significant increase in the hazard ratio (HR) for both acute GVHD [HR 1.21, 95% confidence interval (CI) 0.81–1.81] and severe acute GVHD (HR 1.27, 95% CI 0.55–2.89) in the PBPC arm of the trial [29]. Other trials have reported non-significant increases [32,36] or similar risks in the PBPC and BMT groups [30,31,34], with only one small trial demonstrating a statistically significant increase in acute GVHD in the BMT arm [33]. Two meta-analyses found that the relative risk for acute GVHD after PBPC transplantation was 1.16-fold greater (p = 0.006) [37] or 1.14-fold greater (p = 0.2) [38] compared with BMT. The latter meta-analysis demonstrated a statistically significant increase in severe acute GVHD after PBPC transplantation [odds ratio (OR) 1.13, p = 0.03] [38].

In unrelated donor transplantation, initial small phase II studies of PBPC transplantation with retrospective comparisons with BMT did not demonstrate differences in the rates of acute GVHD [39,40]; however, a large retrospective review of over 1300 patients from the Center for International Blood and Marrow Transplant Research (CIBMTR) database demonstrated that acute GVHD may be more prevalent (56% vs. 46%, p < 0.001) after PBPC transplantation than BMT for leukemia and myelodysplasia [41]. In the largest prospective comparison of BMT and PBPC transplantation in unrelated donors, 551 transplant recipients were randomized to receive either PBPC transplantation or BMT. In this study, the cumulative incidence of acute GVHD (approximately 50%) and severe acute GVHD was no different between treatment groups [42].

Umbilical cord blood (UCB) transplantation is associated with the lowest relative rates of acute GVHD given the multiple HLA mismatches commonly encountered. This difference in acute GVHD incidence is likely attributable to the paucity and skewing of T-cell subsets found in UCB units. Since T cells are found in much higher concentrations in PBPC grafts, it is commonly assumed that this accounts for the differences in GVHD outcome between bone marrow (BM) and PBPC grafts [43–46]. The fact that either in vivo or ex vivo T-cell depletion is associated with reduced rates of acute GVHD is the strongest evidence correlating this cellular subset and the pathogenesis of acute GVHD [47,48]. The role of specific T-cell subsets remains controversial, with some investigators demonstrating important correlations between $CD8^+$ T-cell content [46,49,50] and $CD4^+CD25^+$ regulatory T-cell content [51–55] to be important predictors of the occurrence of acute GVHD.

The number of $CD34^+$ progenitors in a granulocyte colony-stimulating factor (G-CSF)-mobilized PBPC graft is generally higher than in a BM harvest [56]. The dose of $CD34^+$ progenitors has been shown to affect the development of chronic GVHD [45,57], but this association is less clear for acute GVHD [43,45,58–60]. Similarly, the contribution of other cellular subsets contained within a graft to the incidence of acute GVHD remains unknown.

Donor–recipient clinical factors

Both donor and recipient age can influence the occurrence of acute GVHD. In a large analysis of NMDP donor–recipient pairs, increasing donor age was associated with an increased incidence of severe acute GVHD [61]; however, a CIBMTR analysis did not associate donor age with GVHD occurrence [62]. The association of increasing donor age and acute GVHD is also noted among pediatric transplant recipients, where rates of acute GVHD are typically lower [63], possibly related to the presence of a functional thymus in young people. Increasing recipient age is also a known risk for GVHD, but since sibling ages are often closely linked, it has been difficult to demonstrate the independent effect of donor age on GVHD incidence in matched, related donor transplantation. For older recipients, however, it appears that older matched sibling donors remain preferable to younger matched unrelated donors [64].

Donor–recipient gender mismatching and donor parity are associated with an increased risk of acute GVHD, with male recipients of female donor grafts having the highest rates of GVHD [21–23,63,65]. The pathogenesis of this phenomenon is due to the recognition of Y chromosome-encoded antigens by female donor T cells. Parity, by virtue of maternal alloimmunization to fetal minor antigens, would be expected to be associated with vigorous anamnestic-type GVHD responses after transplantation. More recent analyses in matched related donor transplantation and in RIC transplantation, however, failed to note an impact of donor gender [66,67] or age on acute GVHD [67].

The influence of ABO blood type on acute GVHD remains controversial. ABO glycotransferase peptides may act as minor histocompatibility antigens and stimulate allogeneic T-cell responses [68]. A large CIBMTR analysis of 3103 donor–recipient pairs demonstrated an increased risk of severe acute GVHD among bidirectional ABO-mismatched pairs (HR 1.869, $p = 0.006$) [69]; however the recent NMDP analysis associated ABO mismatch only with overall mortality, and not acute GVHD [61], and several smaller studies were not able to replicate this finding [53–55]. Since ABO incompatibility has other consequences on graft processing and transfusion requirements after transplantation, it is often considered in the search strategy in unrelated donor transplantation.

Donor and recipient cytomegalovirus (CMV) serostatus may also influence the rates of acute GVHD. For CMV-seronegative BMT recipients, matching with seronegative donors also appears to reduce the risk of both CMV infection and GVHD [21].

Non-HLA genetic factors

A higher incidence of acute GVHD has also been observed with HLA-matched unrelated donors compared with matched, related donors, necessarily implicating minor or non-HLA antigens in the pathogenesis of GVHD [70]. Minor HLA (mHA) antigens, short peptides presented in the context of HLA, have been identified and sequenced, and disparities among mHAs appear to correlate with the risk of GVHD in adults given HLA-identical donor grafts [71–74]. The importance of mHAs is further supported by the observed lower rate of GVHD in populations that feature genetic homogeneity [75]. In more genetically heterogeneous racial groups, data are less consistent concerning increased rates of GVHD [76–78]. Disparities in antigens with presentation restricted to certain class I and II alleles have been associated with GVHD, demonstrating that altered peptide–ligand binding may have profound effects on alloreactivity [79,80]. Even within the HLA gene complex on chromosome 6, there is evidence that there are relevant transplant mHA genes present. HLA haplotype matching has demonstrated that mismatching of HLA haplotypes is associated with an increase in acute GVHD [81].

Polymorphisms in genes [such as interleukin (IL)-2, IL-6, IL-10, the tumor necrosis factor (TNF) superfamily, and others] that lead to altered expression and levels of cytokines have been linked to differences in acute GVHD incidence (reviewed by Chien et al. [82]), presumably by modulating inflammation in the context of alloimmunity. An additional group of distinct polymorphisms that occur in the natural killer (NK) cell receptor and ligand group, the KIR family, have been linked to differences in both GVHD and relapse rates after transplantation [83,84]. The genes involved in the metabolism of methotrexate have been linked to toxicity and GVHD after allogeneic transplantation [85–87]. Finally, genes with only loose associations with the immune system can also influence rates of GVHD [88–92]. Currently, the presence of cytokine polymorphisms is not ascertained prior to allogeneic transplantation; however, several investigators have suggested that search strategies that include donor genotype of cytokines and other relevant genes should be incorporated into search strategies [93–95].

Tolerance

Chapter 12 reviews the mechanisms of graft–host tolerance after allogeneic HCT. Tolerance can be achieved by elimination (clonal deletion) in the thymus of host reactive cells; accordingly, thymic damage could abrogate self-tolerance [96,97]. Alternatively, functional suppressor $CD4^{+}CD25^{+}FoxP3^{+}$ regulatory T cells may be important in transplantation tolerance [98], and strategies to expand or transfer these T cells selectively to abrogate experimental acute GVHD have been developed [99]. Tolerance can also be attained via the transplacental bidirectional passage of maternal and fetal antigens during pregnancy. In this fashion, tolerance to non-inherited maternal antigens (NIMAs) in utero develops [100]. In experimental and human models of haploidentical transplantation, transfer of stem cells from an offspring to a mother or vice versa results in less acute GVHD than transplantation to or from the father, suggesting that NIMA-induced tolerance exists. This tolerance may be dependent on T cells [101]. Consistent with this finding is that among haploidentical sibling transplants, mismatch for non-inherited paternal antigens (NIPAs) appear associated with higher rates of GVHD, suggesting that exposure to maternal HLA antigens in utero could have a lifelong effect on subsequent immune responses [102,103]. Similarly, in UCB transplantation, when maternal HLA-typing is known, the selection of a NIMA-matched UCB unit is associated with improved outcome [104,105].

Conditioning regimen intensity and immunomodulation

The pathophysiology of acute GVHD, reviewed in Chapter 13, describes an afferent activation loop of conditioning-related tissue injury leading to acute GVHD. As such, it has been postulated that lower intensity preparative regimens, by virtue of causing less tissue injury and lower concentrations of elucidated cytokines, would be associated with a reduced incidence of acute GVHD. In a retrospective single-center review of 238 patients who underwent reduced-intensity compared with myeloablative transplantation, the hazard ratio for grade II–IV acute GVHD was 1.73 ($p = 0.015$) despite similar GVHD prophylaxis in both arms [106]. Similarly, the EBMT noted a 40% reduction in the incidence of acute GVHD among 315 reduced-intensity conditioning recipients when compared with over 400 myeloablative conditioning recipients ($p = 0.01$) [107]. A more recent CIBMTR analysis analyzed GVHD risk by grouping conditioning intensity, stem-cell source, and the use of total body irradiation (TBI), and was able to demonstrate a lower incidence of acute GVHD among unrelated donor recipients who received RIC conditioning when compared with myeloablative, TBI-based PBPC grafts [62]. Even among patients undergoing high-dose conditioning, the intensity of the regimen may influence acute GVHD outcomes. Among HLA-identical transplant recipients who received GVHD prophylaxis with methotrexate and cyclosporine, acute GVHD developed in 48% of patients given 1575 cGy TBI, compared with 21% of patients given 1200 cGy TBI ($p = 0.02$) [108]. An alternative hypothesis linking conditioning intensity and acute GVHD is that more intensive conditioning more effectively eliminates host cells and prevents the development of mixed donor–host chimerism, which has been associated with a decreased probability of GVHD [109,110].

Microbial environment

The microbial milieu of the host may influence the development of GVHD. Compared with conventionally housed, irradiated mice, enteric GVHD is significantly reduced in germ-free mice given incompatible marrow [111]. Human studies confirmed this gnotobiotic effect [112,113]; however, decontamination of the human GI tract using broad-spectrum antibiotics may be associated with an increased susceptibility to fungal overgrowth of the GI tract [114]. Microorganisms could act as triggers of GVHD, by sharing antigenic epitopes with gut epithelial cells, by activating latent virus-inducing antigens on cell surfaces to become targets of alloreactivity [115], or by direct activation of Toll-like receptor (TLR) or non-obese diabetic (NOD)-like receptors on epithelial cells [116]. The effect of GVHD on the intestinal microbiome has also been studied, with marked shifts noted in intestinal microflora occurring in patients with active GVHD [117]. One postulated mechanism for these changes is the targeted destruction of Paneth cells in the intestinal mucosa, leading to a reduction in locally produced antimicrobial α-defensins [118]. Changes in gut microflora are associated with inflammatory changes in the intestinal mucosa, which in turn leads to translocation of bacteria across the mucosal barrier into the bloodstream, elaboration of lipopolysaccharide (LPS) in the circulation, and an increase in cytokine effectors of GVHD [119,120].

Laminar airflow protective isolation with gut decontamination has been shown to decrease the incidence of acute GVHD and improve survival in patients with aplastic anemia [112], but improved outcomes have not been generalizable to all transplant scenarios [121,122]. Randomized clinical trials of antimicrobial prophylaxis demonstrate a reduction in GI GVHD after administration of either antifungal prophylaxis with fluconazole compared with placebo [123], or anaerobic intestinal decontamination with metronidazole plus ciprofloxacin compared with ciprofloxacin alone [113]. Keratinocyte growth factor (KGF) has specificity for gut epithelial cells and can prevent epithelial injury from chemoradiotherapy, reduce levels of LPS and TNF, and decrease enteric GVHD in animal models [124]. However, the use of KGF after transplantation has not been shown to reduce acute GVHD in a randomized study [125].

Clinical features of acute GVHD

Cutaneous acute GVHD

The skin is the most commonly involved organ in acute GVHD, affecting over 75% of acute GVHD patients, and is the sole manifestation in 44% of acute GVHD patients [126]. Acute GVHD presents as a maculopapular exanthem, and may be asymptomatic, pruritic, or painful [127]. It may involve the palms and soles, which helps differentiate the rash of acute GVHD from a drug eruption, which generally spares these areas. The characteristic predilection for these sites appears related to concentration of epidermal stem cells in the rete ridges [128]. As the rash intensifies, confluent involvement ensues. In its most severe form, bullae formation ensues and epidermal necrosis with desquamation occurs, mimicking toxic epidermal necrolysis. The bullae contain sterile serous fluid, and unless the acute alloreactive inflammatory reaction has abated, the regenerating skin exposed by the bullae also may be erythematous.

Gastrointestinal acute GVHD

The GI tract is the second most commonly involved organ in acute GVHD, with up to half of individuals being affected [126]. In general, signs of enteric GVHD develop as the chemoradiotherapy effects resolve following the first several weeks after transplantation; however, these syndromes may overlap, making an early diagnosis difficult. Symptoms of acute GVHD of the distal small bowel and colon include profuse watery diarrhea, intestinal bleeding, crampy abdominal pain, and, in its severest form, ileus. The diarrhea is often green, mucoid, watery, and mixed with exfoliated cells, forming fecal casts. Upper GI tract GVHD is associated with anorexia, nausea, and dyspepsia; patients with upper GI disease may not manifest lower GI tract involvement. In the initial description of upper GI GVHD, 13% of related donor recipients and 31% of unrelated donor recipients were noted to be affected [5]. Importantly, the occurrence of isolated upper GI GVHD did not influence survival outcomes, but upper GI GVHD is now included in the modified Glucksberg acute GVHD grading system.

Imaging of the GI tract using computed tomography often reveals diffuse edema, but this finding is non-specific and should be evaluated with endoscopy and biopsy. Endoscopic findings of enteric GVHD range from normal to extensive edema and mucosal sloughing. Lesions may be most prominent in the cecum, ileum, and ascending colon, but may also involve the stomach, duodenum, and rectum. Gastrointestinal endoscopy and biopsy are mandatory for the diagnosis of upper GI tract disease [5,129], since anorexia and nausea are common symptoms of conditioning-related injury. Endoscopy and biopsy are recommended for the diagnosis of lower GI tract disease in order to exclude other diagnoses, such as viral enteritis.

Hepatic acute GVHD

The liver is the least commonly affected organ in acute GVHD, with less than 20% of acute GVHD patients having hepatic involvement [126]. Cholestatic jaundice is the most common manifestation; however, a concomitant or isolated transaminitis is not uncommon [130–134]. When severe, hepatic failure with encephalopathy may occur. Percutaneous or transjugular liver biopsy is recommended for the diagnosis of hepatic GVHD, when feasible, as there are no imaging studies that can differentiate reliably hepatic GVHD from other causes of liver dysfunction.

Other findings

Ocular symptoms have been described in patients with acute GVHD [135–138]. Manifestations may include photophobia, hemorrhagic conjunctivitis, pseudomembrane formation, corneal ulceration, and lagophthalmos. Involvement of the central nervous system with acute GVHD has been postulated to occur [139,140], although in most cases the definite etiology of the central nervous system pathology cannot reliably be ascribed to an alloimmune effect, with infections and calcineurin inhibitor-induced leukoencephalopathy as the primary diagnostic alternatives. The syndromes of diffuse alveolar hemorrhage and idiopathic pneumonia syndrome are more common among individuals with acute GVHD [141], but whether this in fact represents a true pulmonary manifestation of acute GVHD is unclear. The kidney appears to be susceptible to alloimmune attack in the context of chronic GVHD; however, acute GVHD involving the kidney has not been reported, although there is an association between transplant-associated thrombotic microangiopathy and acute GVHD [142,143]. Thrombocytopenia and anemia have been reported in patients with GVHD and failure of platelet recovery was shown to be 3.5-fold more common in patients with acute GVHD [144,145], with persistent thrombocytopenia having an adverse prognosis [146].

Diagnosis and differential diagnosis

Acute GVHD is a clinicopathologic syndrome with clinical features that may be difficult to distinguish from other early post-transplantation events. For example, the skin rash of acute GVHD is often confused with eruptions related to the effects of chemoradiotherapeutic conditioning, allergic reactions to medications, or viral exanthems. Similarly, the pattern of hepatic enzyme perturbation may be difficult to distinguish from venocclusive disease (VOD) of the liver or viral hepatitis. Complicating the diagnosis is that many of these complications may coexist. The nausea and anorexia of upper GI GVHD and diarrhea of lower GI GVHD are often indistinguishable from conditioning-related injury and intestinal infection with agents such as *Clostridium difficile*, *Candida*, and CMV. Occurring around the time of neutrophil engraftment, an engraftment syndrome, consisting of fever in the absence of infection, diffuse erythroderma, and non-cardiogenic pulmonary edema may also be difficult to distinguish clinically from acute GVHD [147].

Biopsy of the target organs of GVHD (reviewed in Chapter 26) is often obtained for diagnostic confirmation; however, the diagnosis remains largely a clinical one, and therapy often must be initiated before the results of biopsies are known. The utility of skin biopsy in the diagnosis of acute GVHD is questionable in retrospective reviews [148–150]. Similarly, biopsy of the lower and upper GI tract may be difficult to interpret early after transplantation, since the apoptotic changes associated with acute GVHD can often be confused with conditioning-related injury. However, viral or other infectious etiologies of diarrhea after transplantation are more readily distinguished. Biopsy of the liver is often indicated, as the histologic findings of acute hepatic GVHD, including portal triad inflammation, are often easily distinguishable from the findings of VOD of the liver, viral hepatitis, or the cytotoxic effects of medications, unless massive necrosis obscures the diagnostic picture.

Prediction and prognostication of acute GVHD

The role of *in vitro* functional assays to predict the occurrence of acute GVHD is largely historical, with mixed lymphocyte reaction testing no longer being routinely performed. More relevant now are biologic assays that can predict the occurrence of GVHD in advance of clinical features. Several biological markers (biomarkers) of acute GVHD have been postulated to predict the occurrence of acute GVHD better than clinical acumen. Assays for single inflammatory molecules such as TNF-α [151], IL-13 [152], or the soluble IL-2 receptor α chain (sIL-2Rα) [153], or markers of GVHD-target tissue injury (Elafin, REG3α) [154], most often discovered in proteomic assays, may, in the future, be the best markers of acute GVHD, but at present are experimental in nature.

In addition to their potential usefulness to predict GVHD occurrence, some of these biomarker panels have now been used to follow patient progress and to predict outcomes. In a prospective validation study, a six biomarker panel (sIL-2Rα, TNF-α, HGF, IL-8, Elafin, and REG3α) predicted day 28 therapy unresponsiveness and day 180 mortality [155]. However, simple clinical factors may also be useful. Response to steroids and outcome of acute GVHD are correlated with the initial GVHD grade at presentation [3]. Long-term survival for patients with grade 0–I disease approaches 50%, whereas for those with grade IV disease, the long-term survival rate has been reported to be as low as 11% [156]. Response to treatment is also a key predictor of outcome, as mortality in patients with grade II–IV acute GVHD is lowest in those who achieve a complete response to initial treatment (Figure 83.1) [13,156,157]. At least two large analyses have suggested that day 28 response to therapy correlated best with non-relapse mortality and survival [158,159], suggesting that this should be the end-point of acute GVHD clinical trials. A very early response, as evidenced by the ability to begin a steroid taper on day 5 of therapy, is associated with a favorable prognosis [160]. It is likely that early responders do better at least in part because the steroid taper begins sooner and reduces the risk of complicating opportunistic infections, a common cause of death even among responders. In general, skin disease responds promptly, but lower GI tract involvement responds poorly to therapy [157]. This may reflect the fact that the regeneration of a denuded intestinal mucosa requires days to weeks to occur and the use of escalating immunosuppression during this period can result in fatal infections. Other risks for failure of initial therapy and adverse outcome include early onset of GVHD, HLA disparity, and age [13,157], and also protean factors such as caloric intake and performance status [161].

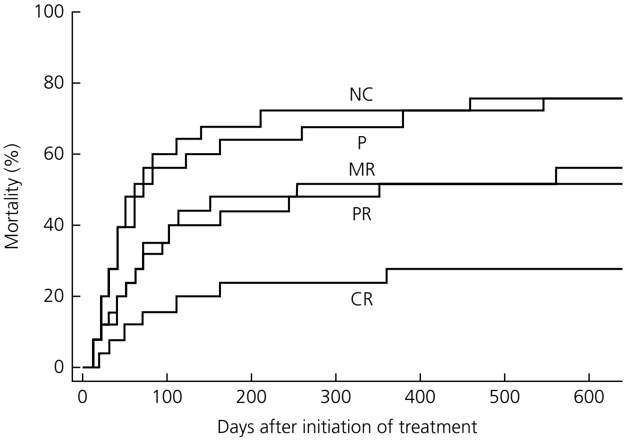

Figure 83.1 Non-relapse mortality following primary therapy for acute GVHD [13]. CR, complete response; PR, partial response; MR, mixed response; P. progression; NC. no change.

Therapy of acute GVHD

Primary therapy

The mainstay of therapy for acute GVHD is corticosteroids, with the route of administration (topical, oral, or intravenous) determined by the severity of acute GVHD and the degree of organ involvement. Corticosteroids are lympholytic and decrease the inflammatory cytokine cascades that propagate acute GVHD. Other agents have been utilized as front-line therapy, but none is superior to corticosteroids [13,162].

There is substantial center and investigator variability regarding the stage of acute GVHD that should be treated and the dose of corticosteroids to be used, particularly in early-stage GVHD. Cutaneous involvement with less than 50% body surface area involvement in the absence of hepatic or GI involvement (stage 1 or 2 skin disease, overall grade I acute GVHD) can often be treated with the topical administration of medium- or high-potency glucocorticoids alone; however, individuals with multiorgan involvement, and also some individuals with near 50% body surface cutaneous involvement, require systemic corticosteroid administration. The recommended initial dose of corticosteroids for grade II–IV acute GVHD is 2 mg/kg/day of methylprednisolone, or an equivalent steroid [163,164]. Initial steroid doses lower than 2 mg/kg/day have been analyzed retrospectively. In an analysis of 733 patients, no difference in adjusted hazard ratios for non-relapse mortality, recurrent or progressive malignancy, overall mortality, and extensive chronic GVHD were noted when doses of 1 and 2 mg/kg/day were compared; however, the former group was comprised predominantly of patients with grade I–II acute GVHD [165]. Initial doses of corticosteroids higher than 2 mg/kg/day were not been associated with improvement in response rates. In a prospective trial comparing 2 with 10 mg/kg/day of methylprednisolone in 94 patients with grade II–IV acute GVHD, response rates, progression to grade III–IV disease, non-relapse mortality, and overall survival were similar in both treatment groups [160].

For steroid-responsive acute GVHD, treatment is generally continued until complete resolution of signs and symptoms of acute GVHD and for at least 1–2 weeks thereafter. A gradual taper of the corticosteroid dose is then initiated, generally at no greater than a 10% reduction per week, but modified by factors such as the durability of the response to steroids and the toxicity of high-dose steroids. In a prospective trial, patients with acute GVHD who were responding by day 14 of corticosteroid treatment were randomized to a fast taper of corticosteroids over 86 days ($n = 14$) or a slow taper over 147 days ($n = 16$). The median time to acute GVHD resolution was 42 days (range 12–74 days) in the short treatment group, compared with 30 days (range 6–30 days) for the long taper schedule ($p = 0.01$), but without significant differences in the number of patients with acute GVHD flares, chronic GVHD, median dose of corticosteroid administered, infection, or death, suggesting that lower total cumulative doses of steroids appear equally effective and might minimize steroid-related complications [166].

The response rate to corticosteroid therapy in large retrospective reviews was approximately 50% [13,157], although it was higher in smaller clinical trials [167]. Durable responses are even less common. The complete response rate to corticosteroids is low enough to have prompted investigators to examine the role of additional immunosuppressive agents in the initial therapy of acute GVHD. The most widely studied agent in this setting is antithymocyte globulin (ATG). Phase II data demonstrated the response rate to steroids and ATG to be 67–80% [168,169]. In a randomized trial of prednisone with or without ATG ($n = 100$), no difference in response rates (76% in both arms) or survival at 1 and 2 years was noted, but infectious morbidity was higher in the combined immunosuppression group [167]. Lee et al. randomized 102 patients to receive the monoclonal anti-CD25 antibody daclizumab (1 mg/kg) on days 1 and 4 and weekly thereafter or placebo in conjunction with corticosteroids. Response rates were similar in both groups (53 vs. 51%), but survival at 100 days and 1 year was inferior in the daclizumab group [170]. Randomized trials have similarly demonstrated no benefit to the addition of the anti-IL-2 receptor antibody inolimomab [171], an anti-T-cell ricin-A-chain immunotoxin [172], or the monoclonal TNF-α antibody infliximab [173] when added to corticosteroids. In order to minimize the systemic effects of long-term high-dose steroids, corticosteroids with or without oral beclomethasone were tested in a small randomized trial and demonstrated benefit [174], but these advantages were not noted in a larger randomized trial, which was halted after an interim analysis suggested futility.

The Blood and Marrow Transplant Clinical Trials Network (BMT CTN) performed a randomized phase II trial of corticosteroids in combination with one of four promising agents [denileukin diftitox, etanercept, mycophenolate mofetil (MMF), and pentostatin]. The highest response rates were in patients treated with MMF [175], leading to a randomized phase III study of corticosteroids alone or with MMF. This trial was halted with 236 enrolled patients when the experimental and control arms demonstrated similar rates of GVHD-free survival 56 days from randomization (60.5% vs. 52.2%, $p = 0.78$) without differences in chronic GVHD incidence, severe infections, or overall survival in an interim analysis [176]. Hence there is no evidence at present that strategies using additional immunosuppressive agents will improve outcomes beyond single-agent prednisone.

Secondary therapy

Patients in whom initial therapy fails (commonly defined as progression of acute GVHD after 3 days, no change after 7 days, or incomplete response after 14 days of methylprednisolone treatment) have been given a variety of salvage regimens. There is no accepted standard for salvage treatment, and therapy of steroid-resistant acute GVHD remains unrewarding despite seemingly high response rates due to the risks of infection during intense immunosuppression.

The agent used most commonly in the setting of corticosteroid failure is ATG [177,178]. ATG use has been associated with response rates between 30 and 54%, but provides long-term survivorship in only 5–20% of treated patients [179–182], with earlier administration associated with improved survival [182]. Other pan-T-cell depleting strategies, including the monoclonal murine anti-CD3 antibody OKT3 and the non-mitogenic non-Fc-binding anti-CD3 antibody visilizumab, have been tested, but both of these were associated with excess rates of Epstein–Barr virus (EBV) reactivation and post-transplant lymphoproliferative disorder (PTLD) [183–186]. The anti-CD52 monoclonal antibody alemtuzumab, which targets all T cells and also antigen-presenting B cells and dendritic cells, has also been reported to be effective as therapy of steroid-refractory acute GVHD [187–189].

Targeting only activated T cells, antibody therapy directed against the α-subunit of the IL-2 receptor (CD25) has been attempted for more than 30 years, using the original anti-Tac antibodies [190–192], a murine antibody (BT563, inolimomab) [193–195], a chimeric murine/human monoclonal antibody (basiliximab) [196–198], and a humanized antibody (daclizumab) [199–203]. The utility of most of these agents is largely historical, since only basiliximab is currently available for use in the United States. In the original dose escalation trial, there was a response rate of 40%, with a predilection for improvement in cutaneous and GI disease [199]. Subsequently, a response rate of 50% was shown in a small cohort of patients with grade III–IV acute GVHD [203], and the largest series of patients reported demonstrated a complete response rate of 29% for patients treated with daclizumab weekly for five consecutive weeks, and a complete response rate of 47% for patients treated on a more accelerated schedule (1 mg/kg on days 1, 4, 8, 15, and 22) [201]. More recent retrospective analyses confirmed the high response rates, but poor long-term survival [200]. A large retrospective review spanning 10 years of experience noted a response rate of 42% by day 30 for inolimomab, with lymphopenia, early use, and grade IV disease as predictors of adverse outcome [195]. In phase II studies using different doses and schedules of basiliximab, the overall response rate was uniformly high (71–82.5%), with the complete response rate varying between 17.5% and 53% [196–198]. Also targeting the IL-2 receptor, denileukin diftitox is a recombinant fusion protein comprised of amino acids 1–133 of IL-2 fused to the membrane translocation and catalytic domains of diphtheria toxin. In a phase I study in steroid-refractory acute GVHD, 71% of patients responded to therapy, with 46% attaining a complete response at the MTD (9 μg/kg, days 1, 3, 5, 15, 17, and 19) [204]. A similar dose escalation trial that administered 4.5 μg/kg daily for 5 days followed by weekly therapy for 1 month showed a complete response rate of 41% at 36 days [205]. Other potential activated T-cell surface targets include CD147 (targeted by the antibody ABX-CBL), a member of the immunoglobulin superfamily, which is also found on B cells, monocytes, and dendritic cells [206]. Although active, this agent demonstrated inferior survival when compared with ATG in a multicenter, randomized phase III study [207].

Targeting the inflammatory cytokines that lead to T-cell activation and proliferation has been attempted in secondary GVHD treatment. Busca et al. treated 13 patients with steroid-refractory acute GVHD with etanercept, a genetically engineered molecule comprising two p75 extracellular domains of the human TNFα receptor fused with human IgG1, administered subcutaneously twice weekly for 4 weeks. Six of 13 responded (46%), with five attaining a complete response [208]. The chimeric antibody infliximab neutralizes TNFα and lyses cells that produce it, and has been used more extensively than etanercept. Initial case series and dose escalation trials documented the potential effectiveness of this agent [209–211], and larger series demonstrated response rates of 59–67%, with a predilection for improvement in GI GVHD [212,213], but with a high incidence of fungal infection [213,214]. Combination therapy with anti-T-cell therapy and cytokine-directed therapy has also been reported [215–219]. Other cytokines, including IL-5, IL-6, and IL-12/IL-23, are potential targets for GVHD therapy.

Agents that inhibit the proliferation of T cells are useful in the prevention and treatment of GVHD. In a phase I dose escalation study of pentostatin, an adenosine deaminase inhibitor, for steroid-refractory acute GVHD, the maximum tolerated dose (MTD) was 1.5 mg/m^2, and the overall response rate was 77% [220]. Less promising long-term results were reported recently by others [221,222]. MMF similarly suppresses T-cell proliferation by reversibly inhibiting purine synthesis; however, the use of this agent was associated with poor long-term survival in one series [223]. Sirolimus, an inhibitor of the mammalian target of rapamycin, is a T-cell immunosuppressant that inhibits DNA transcription, DNA translation, protein synthesis, and cell cycling [224]. Sirolimus may also be immunosuppressive through multiple alternative pathways. Benito et al. reported that 12 of 21 steroid-refractory patients (57%) had an objective response to sirolimus (five complete response, seven partial response); however, toxicity was limiting in this series [225]. Using more stringent serum levels, Hoda et al. demonstrated a 76% response rate (44% complete response rate) with acceptable toxicity and 44% survival at 1 year [226].

Extracorporeal photopheresis (ECP) has been used in the management of refractory acute GVHD. Postulated mechanisms of action of ECP, in addition of apoptosis of treated CD8$^+$ T effector lymphocytes, include a decrease in the production of proinflammatory cytokines and an increase in production of anti-inflammatory cytokines, both of which lead to a lower ability to stimulate T-cell responses, mediated in part by an increase in regulatory T cells [227,228]. Greinix et al. reported a 60% complete response rate to ECP, although there were no responders with GI GVHD [229], and Perfetti et al. reported response rates of 70, 42, and 0% for patients with refractory grade II, III, and IV GVHD respectively [230]. A similar approach used ultraviolet A light with a psoralen sensitizer to control refractory cutaneous GVHD, where high response rates were noted [231–233].

The use of cellular therapy to treat resistant acute GVHD has been explored. Mesenchymal stem cells (MSCs) are immunosuppressive, and transplantation of these cells from haploidentical or third-party donors improved GVHD in experimental models [234]. The first report of haploidentical MSC infusion for therapy of resistant acute GVHD was by LeBlanc et al., who obtained a single favorable outcome [235]. Since then, other case series reporting the successful use of MSCs in resistant visceral acute GVHD have been reported, with a notion that these cells may help repair the damaged organ, thus speeding up recovery from GVHD even further. Unfortunately, a large randomized trial failed to demonstrate an advantage to MSCs when added to conventional therapy in the treatment of steroid-refractory acute GVHD [236].

There are other experimental approaches to the management of refractory acute GVHD, including intra-arterial steroid [237–239] or methotrexate [240] infusion for GI and hepatic GVHD, and modulation of T-cell responses using alefacept [241] and IL-1 receptor-blocking antibodies [242]; however, all of these approaches remain experimental.

Supportive care

In addition to immunosuppressive therapy, supportive care is critical for the favorable outcome of acute GVHD. Organ-specific supportive measures for the skin include the use of topical emollient therapy and meticulous wound care, including care in a burn unit when indicated. For the GI tract, gut rest and parenteral hyperalimentation are required. Antimotility agents such as loperamide are often employed. Octreotide or other somatostatin analogs may be of benefit in controlling the secretory component of GI GVHD [243,244]. The use of ursodeoxycholic acid has been advocated as a supportive measure in hepatic acute GVHD, and hepatotoxic agents should be avoided.

Systemic supportive measures include the judicious use of antibiotics for proven or suspected infections, the routine use of antiviral prophylaxis against herpesviruses, and routine monitoring for CMV reactivation. Finally, routine antifungal prophylaxis with extended spectrum azoles or echinocandins with activity against *Aspergillus* sp. and other molds is recommended [245], as infectious morbidity during immunosuppressive therapy for GVHD therapy is a major cause of morbidity and mortality.

Special scenarios

Hyperacute GVHD

Hyperacute GVHD is a very rare complication of allogeneic HCT. Clinically similar to traditional acute GVHD, hyperacute GVHD occurs earlier, and often several days prior to engraftment, although no standard definition exists. The pathophysiology of hyperacute GVHD remains unclear. It has been postulated to be caused by mature, immunocompetent cells transferred with the stem-cell product, including natural killer T (NK-T) cells [246]. Risk factors for hyperacute GVHD include mismatched or unrelated donor transplantation, high-dose conditioning, donor–recipient gender mismatching, second transplantation, and the lack of prophylactic immunosuppression [247–250]. Therapy for hyperacute GVHD is similar to that for acute GVHD, and although it is often less successful, the long-term outlook for hyperacute GVHD appears no different than for patients with traditional acute GVHD [247,248].

Autologous GVHD

Histocompatibility differences between donor and recipient may not always be needed to produce GVHD; instead, inappropriate recognition of self-antigens may produce a GVHD-like syndrome after autologous HCT [251,252]. In a thymus damaged by conditioning therapy after autologous HCT, HLA class II-bearing cells may be absent and clonal deletion of reactive anti-self cells may not occur. In a series of patients conditioned with alemtuzumab prior to transplantation, a high incidence of autologous GVHD was reported, suggesting that dysregulation of the immune system is involved in the pathophysiology of autologous GVHD [253]. Administration of cyclosporine in the context of thymic damage may further prevent the development of regulatory immune cells and permit the development of autoreactive $CD8^+$ and $CD4^+$ T cells that recognize class II determinants [254]. Cyclosporine administration after autologous transplantation has been given in an attempt purposefully to invoke graft-versus-malignancy effects [255–257].

Clinical involvement of the skin, liver, and GI tract have all been reported in autologous GVHD [258–260], although the incidence of each of these complications is low. Therapy for autologous GVHD is similar to that for classic acute GVHD, with very favorable results with corticosteroids alone. Some have postulated that autologous GVHD may simply be a version of an engraftment syndrome.

Transfusion-associated GVHD

Transfusion-associated GVHD (TA-GVHD) is a rare complication of blood-component transfusion therapy [261]. TA-GVHD has been associated with cellular blood components, thus excluding cryoprecipitate or fresh frozen plasma [261–264]. The incidence of TA-GVHD overall remains elusive, as the disorder is often not recognized and is under-reported, but the pathobiology appears similar to that of GVHD following allogeneic hematopoietic stem-cell transplantation [265,266].

Although immunologically normal recipients may be affected by TA-GVHD, several groups are at a distinctly higher risk. Individuals with congenital immune deficiency disorders, cancer patients receiving immunosuppressive chemotherapy, and surgical patients undergoing major surgical procedures or suffering from severe trauma represent the most commonly affected subjects [263]. Among normal individuals, genetic factors appear to be the most important risk factors [267,268]. In populations with common HLA haplotypes, homozygous extended HLA haplotype donors represent the greatest risk. In this setting, donor cells would not be rejected as foreign by the recipient and could precipitate TA-GVHD [269,270]. In Japan, the incidence is estimated to be approximately 1 in 500 after major cardiothoracic procedures [267].

The clinical features of TA-GVHD are very similar to those of traditional GVHD, although the onset of TA-GVHD is generally earlier than that of traditional GVHD, often occurring 7–10 days after transfusion therapy. The diagnosis can be made by demonstrating circulating T cells of donor origin using chimerism analysis. The one distinguishing clinical feature of TA-GVHD is the development of pancytopenia, which indicates that host marrow and hematopoietic progenitors are an immunologic target of TA-GVHD. Pancytopenia and resultant infectious complications of TA-GVHD are the most common cause of death in TA-GVHD, which often occurs 3–4 weeks after the diagnosis.

Prevention of TA-GVHD is critical. The efficacy of blood-product irradiation has long been recognized, and initial BMT practice routinely employed irradiation of blood products with 1500 cGy [271]. This dose of gamma irradiation from ^{60}Co or ^{137}Cs sources effectively prevents lymphocyte proliferation without adverse effects on blood cell morphology or function [272]. Although there has been variation across individual centers, 97% of institutions surveyed by the American Association of Blood Banks employ doses of 1500–3500 cGy [273]. This practice appeared to be highly effective and only a single case of TA-GVHD has been reported in a patient given blood components irradiated with 2000 cGy from a ^{137}Cs source [274]. Based upon more sensitive limiting dilution assays of T-cell inactivation, more recent studies have called for higher doses of blood-product irradiation and since July 1993, the US Food and Drug Administration (FDA) has required a dose of 2500 cGy to the internal midplane of the canister with no area receiving less than 1500 cGy, with well-defined procedures for quality assurance, dose mapping, and storage times [275–278].

Newer methods to prevent TA-GVHD are under development. Most promising are photosensitizing psoralens and ultraviolet A (PUVA) light designed to inactivate infectious organisms. This technology also cross-links T-cell DNA and in addition prevents their proliferation [279,280]. Lymphocyte depletion of transfused blood products has been attempted; however, the minimum threshold of competent T cells to induce TA-GVHD is still unknown, and there are case reports of individuals developing TA-GVHD despite lymphocyte depletion [281,282].

Therapy of TA-GVHD using agents used to prevent or treat traditional GVHD has rarely been successful, since the pancytopenia is often irreversible, and there is therefore an almost 90% fatality rate associated with TA-GVHD. Despite this, an attempt at immunosuppression using corticosteroids and other immunosuppressive agents is often attempted, sometimes with favorable outcomes [283,284]. Allogeneic HCT is often required to restore hematopoiesis.

Conclusion

Despite a seemingly improved understanding of the biologic mechanisms of acute GVHD, this syndrome is often the first hurdle to challenge the transplant recipient. The diagnosis of acute GVHD remains largely a clinical one, with biopsy of affected organs an important adjunct. After decades of research, the standard therapy for this problem remains simple corticosteroids, although novel approaches to the initial management of acute GVHD are being developed. In addition, there remains no standard for secondary therapy of acute GVHD, as numerous agents have only modest activity in this setting. Unfortunately, most of these approaches are associated with high mortality related to infectious morbidity. Future endeavors in acute GVHD include novel assays for the diagnosis of acute GVHD, preemptive therapy for incipient acute GVHD, and the standardization of therapeutic measures when primary therapy fails.

CHAPTER 84

Chronic Graft-versus-Host Disease – Clinical Manifestations and Therapy

Paul A. Carpenter[1], **Mary E.D. Flowers**[1] **and Steven Z. Pavletic**[2]

Introduction

Chronic graft-versus-host disease (cGVHD) is a pleiotropic syndrome, characterized in 1980 [1], and clinically distinguished from the typical dermatitis, hepatitis, and enteritis of acute GVHD by the reclassification of the 2005 National Institutes of Health (NIH) Consensus Development Project on cGVHD [2]. Thus, the NIH diagnosis of cGVHD requires no reference to timing after transplantation but rather requires the presence of characteristic clinical manifestations resembling collagen vascular diseases that may affect one or multiple sites, including skin, liver, eyes, mouth, gastrointestinal (GI) tract, lungs, serosae, and skeletal muscles. Manifestations that are diagnostic of cGVHD are categorized as "*classic chronic*" regardless of when they occur, those consistent only with acute GVHD but which occur at or after day 100 are defined as "*late acute*" and the concurrent presentation of chronic and acute manifestations defines the "*overlap subtype*" of cGVHD (Figure 84.1). Major causes of cGVHD morbidity include ocular and oral sicca syndromes, contractures, and ulcerations associated with sclerotic cGVHD, progressive airflow obstruction, dysphagia, wasting syndrome, and others related to chronic illness. Infection represents the major cause of mortality and is associated with immune dysregulation, which also includes eosinophilia, circulating autoantibodies, and perturbations in the serum levels of gammaglobulin.

Half of all patients who develop cGVHD are diagnosed within 6 months from transplantation and the remainder develop it within 2 years. cGVHD is the major late determinant of morbidity and non-relapse mortality (NRM) after allogeneic transplantation and is associated with decreased quality of life, impaired functional status, and prolonged duration of immunosuppressive therapy. Nonetheless, its potential benefit is the eradication of malignant cells via a graft-versus-tumor effect that remains poorly understood but an active focus of ongoing research.

After 25 years of limited progress in cGVHD due to deficiencies in our understanding of its biology, diagnosis, staging, supportive care, and response categorization, the 2005 NIH consensus conference energized the field. The fruits of these labors are beginning to emerge, for example, with the early validation results of revised classification schemes, severity scales, and response assessment tools [3–13]. Important 2014 updates to the 2005 NIH consensus reports were published after this chapter was submitted to the publisher and are available in the article by Jagasia et al. [13] and at http://www.asbmt.org/?page=GuidelineStatements.

Risk factors for onset of chronic GVHD

Factors that have consistently been associated with a higher risk for developing traditionally defined cGVHD include preceding acute GVHD, older patient age, the use of female donors for male recipients, donor lymphocyte infusions (DLIs), unrelated or HLA-mismatched donors, and, more recently, the use of granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood cells as opposed to marrow as a source of stem cells [14]. Among them, a prior history of acute GVHD seems to be the most powerful predictor, which is not surprising given the overlap of some, but not all, of these risk factors. A comparative analysis between acute GVHD and cGVHD diagnosed by NIH criteria has shown that total body irradiation is a risk factor for acute GVHD but not for cGVHD [3]. In contrast, mobilized peripheral blood grafts and older patient age increased the risk for cGVHD but not acute GVHD and the impact of female donor into male recipient was greater on cGVHD (Figure 84.2); these associations held after adjustment for prior acute GVHD (data not shown). This suggests that cGVHD is not simply a continuation of acute GVHD and that some differences in the mechanisms of pathogenesis may exist between these syndromes. Among patients with cGVHD, total body irradiation has been identified as a significant risk factor for skin sclerosis, one of the most disabling forms of cGVHD [15].

The incidence of cGVHD varies from 20 to 85%, depending on the presence of aforementioned risk factors and the diagnostic criteria used. After matched sibling transplantation, the incidence of traditionally defined extensive cGVHD at 3 years is 47% after mobilized blood versus 31% for marrow ($p < 0.000001$) [16], frequencies that are similar to those seen in the unrelated donor setting based on the 2-year rates of extensive cGVHD in the randomized Blood and Marrow Transplant Clinical Trials Network (BMT CTN) 0201 study (48% versus 32%, $p < 0.001$] [17]. It is worth noting that rates of NIH-defined cGVHD are lower than for historically defined extensive cGVHD because the latter also includes late acute GVHD (Figure 84.1).

The reason for the increased incidence of cGVHD after mobilized blood allografts is not fully understood. Although mobilized blood contains more than 10 times the number of T cells than marrow, one study showed that the number of infused CD3 positive cells may not correlate with the development of

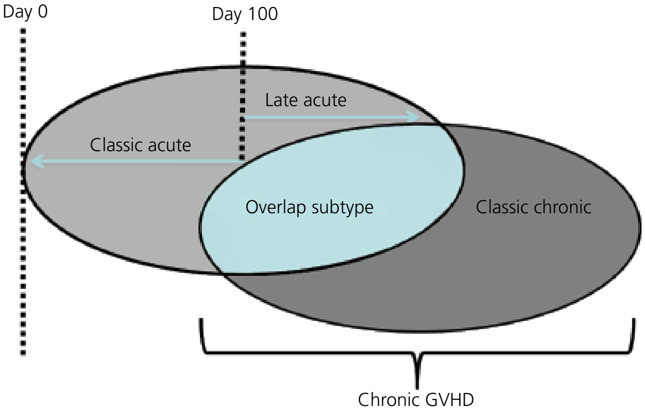

Figure 84.1 Acute GVHD and cGVHD are subcategorized into *classic* acute GVHD (maculopapular erythematous rash, GI symptoms, or cholestatic hepatitis) occurring arbitrarily within 100 days after HCT or DLI, or *persistent, recurrent* or *late* acute GVHD beyond 100 days and typically seen after withdrawal of immunosuppression. Both acute GVHD entities occur without the presence of diagnostic or distinctive cGVHD manifestations. cGVHD subcategories include classic cGVHD consisting only of manifestations attributable to cGVHD (Table 84.1), and acute GVHD and cGVHD overlap syndrome, in which features of acute GVHD and cGVHD coexist.

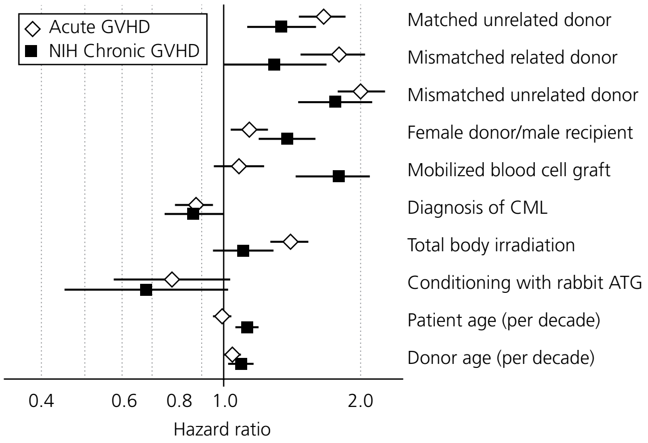

Figure 84.2 Risk profiles for acute GVHD and cGVHD. Factors associated with an increased risk (median HR > 1) or decreased risk (median HR < 1) for development of acute GVHD or NIH cGVHD are shown together with 95% confidence intervals (CIs) for each factor. There were 2355 acute GVHD events and 1022 NIH cGVHD events. Source: Flowers et al 2011 [3]. Reproduced with permission of the American Society of Hematology.

cGVHD [18]. Donor exposure to filgrastim does not appear to be a strong risk factor since rates of cGVHD are lower among recipients of filgrastim-primed allogeneic marrow versus filgrastim-mobilized blood [19]. Although ex vivo T-cell depletion is clearly associated with lower rates of acute GVHD, its effects on cGVHD rates are less clear and these effects may depend on the source of stem cells [20,21]. Early complete donor chimerism seems to be important for developing cGVHD and is frequently delayed after reduced-intensity conditioning (RIC) and may affect the incidence and severity of cGVHD [22]. In summary, although our ability to predict cGVHD has improved, additional improvements in prognostic criteria are still needed and might include biological markers [23].

Risk factors associated with increased non-relapse mortality and inferior survival

Across studies, thrombocytopenia (<100 × 10^9/L) and progressive onset of cGVHD from prior acute GVHD are the two factors most consistently associated with increased risk for late NRM among patients with cGVHD. Other factors at the time of cGVHD diagnosis that have been commonly reported to associate with increased NRM include prednisone dose >0.5 mg/kg/day, hyperbilirubinemia (>2 mg/dL), extensive (>50%) skin involvement, poor Karnofsky performance status, weight loss, intestinal involvement, history of prior acute GVHD grade II–IV, HLA mismatching, and older patient or donor age, among others [24–27]. Several retrospective studies have reported inconsistent results regarding the associations of GVHD subtypes with NRM or overall survival. Three studies reported that NRM was higher, and survival lower, for late acute compared with cGVHD classic or overlap subtypes [28–30], while three other studies reported no differences in outcomes between GVHD subtypes [6,9,31]. Two of these reports did note an independent association of NIH global severity (mild, moderate, severe) with overall survival and NRM [9,31]. A recent prospective longitudinal study of 298 patients by the North American Chronic GVHD Consortium showed that global severity scores at enrollment were associated with NRM ($p < 0.0001$) and survival ($p < 0.0001$) (Figure 84.3), and 2-year overall survival was 62% (severe), 86% (moderate), and 97% (mild) [8].

An earlier registry analysis of over 5000 adults and children with cGVHD was used to develop a 10-variable risk score [age, prior acute GVHD, time from hematopoietic cell transplantation (HCT) to cGVHD, donor type, disease status at HCT, GVHD prophylaxis, gender mismatch, serum bilirubin, Karnofsky score, and platelet count]. Risk groups were identified that predicted 5-year outcomes that stepwise ranged from 5% through to 72% for NRM and 91% down to 4% for overall survival. These results were recently validated in a contemporary population and can be broadly applied [32]. This Center for International Blood and Marrow Transplantation Research (CIBMTR) risk score may not be equally applicable to NIH-defined cGVHD.

These results suggest that intervention studies in cGVHD should consider assigning therapy according to risk group. For instance, patients at low risk for NRM might be preferentially enrolled in studies of new topical or organ-specific therapies, whereas high-risk patients might receive more aggressive systemic therapy.

Risk factors associated with duration of therapy

The results of at least one randomized study indicated that a longer duration of prednisone therapy was needed to treat cGVHD that occurred after transplantation of mobilized blood compared with bone marrow [33]. Results of a multivariate analysis in a large retrospective cGVHD cohort confirmed and extended this observation by showing that the time to stop systemic immunosuppression permanently was longer for recipients of mobilized blood allografts, for male patients with female donors, when HLA-mismatching occurred in the direction of GVHD, for patients with hyperbilirubinemia, or for patients with multiple organ involvement at onset of cGVHD [27]. Time to discontinue immunosuppressive therapy in the absence of recurrent malignancy has been used as a surrogate end-point indicating resolution of reversible cGVHD manifestations. Among patients with cGVHD who do not relapse or die from other causes, the median time to discontinue immunosuppressive therapy differs according to graft source and is just over 3 years for mobilized blood and 2 years for marrow [27].

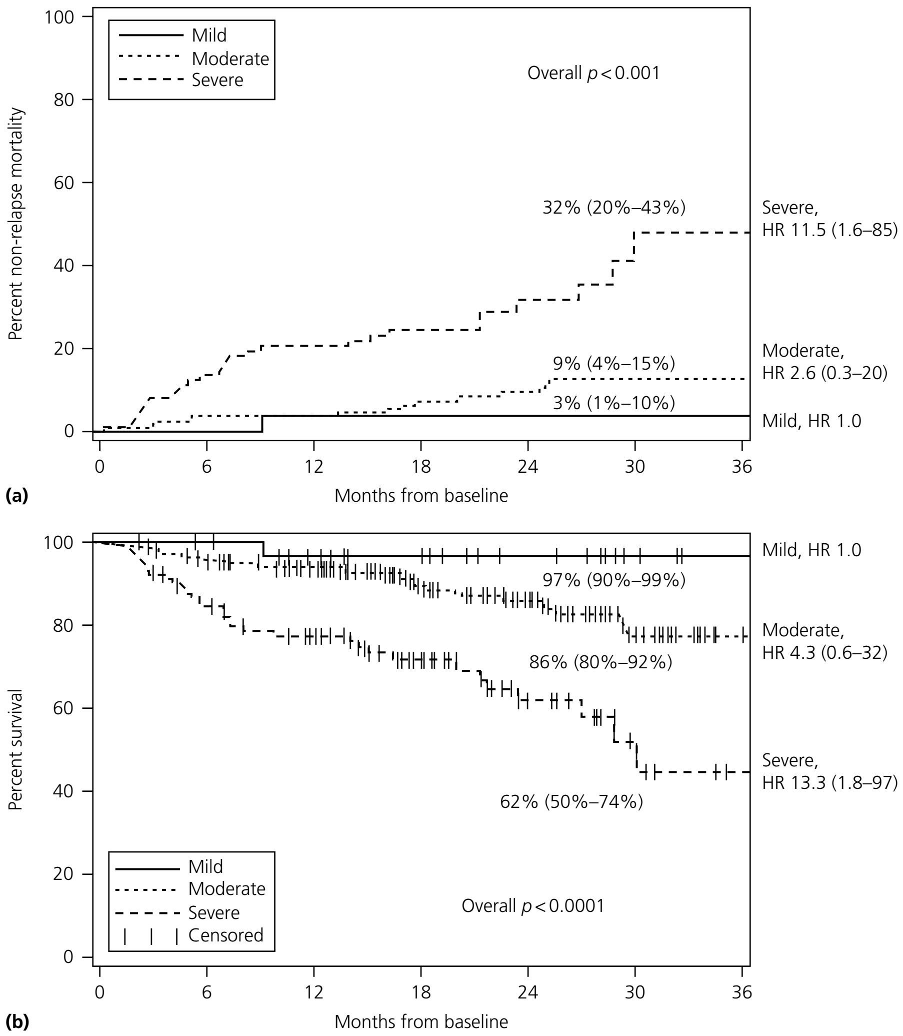

Figure 84.3 Cumulative incidence of non-relapse mortality (a) and Kaplan–Meier plot of overall survival (b) according to NIH global severity at enrollment, and showing 2-year estimates (95% CI). Pathogenesis in humans

The pathophysiology of GVHD in described more fully in Chapter 13. The biology of cGVHD remains elusive even though recent murine and human studies have provided some new insights. Alloreactive T cells are key mediators as supported by observations that cGVHD usually does not occur after autologous or identical twin transplantation. The delayed onset of cGVHD suggests that inciting processes have a long evolution or latency. Thymic dysfunction may play a role in pathogenesis, as supported by older patient age being a predictor for cGVHD and that response rates in children to a given GVHD therapy are often higher than in adult patients. Most investigators consider cGVHD as a disease of immune dysregulation that involves donor-derived immune cells and host cell populations and tissues. Donor-derived T cells are central mediators and the process is both alloreactive (directed against recipient histocompatibility antigens) and autoreactive (directed against antigens present on both donor and recipient) [34]. Thus, cGVHD therapy has traditionally been with T-cell-based immunosuppression and when anti-T-cell globulin is given in the peri-transplant period, a reduced rate of cGVHD has been observed [35]. Once activated, the immune response in cGVHD is thought to proceed without the usual tolerance-promoting mechanisms of thymic or peripheral deletion and immunoregulation [36–38]. This pathologic immune response attacks target tissues directly through cytolytic mechanisms, secretion of proinflammatory and profibrotic cytokines, or promotion of B-cell activation and autoantibody production [34,39]. Inflammation leads to tissue damage, counter regulation and repair with fibrosis, or irreversible organ damage. Although autoantibodies have been detected in some patients with cGVHD, evidence for a causal relationship of these antibodies in cGVHD pathogenesis has not yet been demonstrated. One study suggested the potential involvement of stimulatory antibodies against antiplatelet-derived growth factor alpha receptor (PDGFR), in the sclerotic cGVHD phenotype, based on reported activities of these antibodies to induce fibrosis via induction of PDGFR phosphorylation, reactive oxygen species generation, and the increased expression of α-actin and collagen. Such observations have prompted recent interest in therapy with imatinib, a tyrosine kinase inhibitor of PDGFR, c-KIT, BCR-ABL, and discoidin domain receptor family members 1 and 2 (DDR1 and

DDR2) [40,41]. In addition to antibody production, B cells are involved in important antibody-independent mechanisms such as antigen presentation, cytokine production, and immune regulation, which are thought to be involved in cGVHD. Taken together, targeting B cells with agents such as anti-CD20 monoclonal antibodies (e.g. rituximab) or novel agents targeting B-cell-tropic factors (belimumab and anti-BR3 antibody) are of interest for cGVHD and are under investigation in other more common autoimmune diseases [39]. Finally, new insights about the role of $CD4^+CD25^+FOXP3^+$ regulatory T (Treg) cells in tolerance induction have generated enthusiasm for testing therapies that are thought to promote Treg cell expansion. In one study, the frequency of Treg cells in patients with cGVHD was about half that in the non-cGVHD group but suppressive function of these Treg cells remained normal [38]. This reduction was thought to be physiologically relevant given the low naturally occurring frequency of Treg cells in the blood of healthy individuals yet their critical role in controlling a wide range of immune responses. Perhaps best illustrating this point is the clinical severity of the immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome, which shares a number of features with cGVHD and is caused by FOXP3 mutations that result in a functional deficiency of Treg cells [42]. Therapies such as extracorporeal photopheresis and mammalian target of rapamycin inhibitors (e.g. sirolimus) that promote Treg cell expansion are currently being explored as primary therapy of cGVHD rather than calcineurin inhibitors, which inhibit Treg cell expansion [43–45]. An ongoing randomized phase II/III trial of the BMT CTN (Protocol 0801) is testing the question of sirolimus versus calcineurin-inhibitor-containing therapy. In summary, owing to the diversity and unpredictability of cGVHD, contemporary therapy focuses on global suppression of all or many of the key components of this inflammatory cascade. Although an integrated understanding of cGVHD biology is still lacking, certain of its elements are becoming more evident.

Diagnosis of cGVHD

Manifestations of cGVHD usually present between 3 months and 2 years after allogeneic HCT but about half of all cases develop within the first 6 months. Chronic GVHD manifestations of the classic or overlap subtype can begin before or after post-transplant day 100. When manifestations of acute and cGVHD occur simultaneously, this is referred to as the overlap subtype of cGVHD. Manifestations of acute GVHD alone can develop, persist, or recur long after day 100, and while this has been referred to as "late" acute GVHD, the 2014 NIH Consensus prefers simply "acute GVHD" regardless of its timing. (Figure 84.1). Late acute GVHD is more common after RIC transplantation [46]. For example, liver transaminase elevations, skin erythema, or noninfectious diarrhea that develop while tapering off immunosuppression in the absence of diagnostic features of cGVHD are classified as late acute GVHD regardless of the time after transplantation. GVHD after DLI may present with manifestations of only acute, both acute and chronic ("overlap"), or classic cGVHD alone [47].

The most commonly affected organs reported in North Americans are skin, mouth, and eyes, with more than 50% of patients demonstrating these manifestations (Figure 84.4). Other common disease sites include the liver, lung, GI tract, musculoskeletal system, and female genital organs. Manifestations of cGVHD may be restricted to a single organ or typically 2–3 organs are involved. Obstructive lung disease and sclerotic features of cGVHD most often develop some time after the initial diagnosis of cGVHD.

Standardized criteria for physical signs, symptoms, and laboratory and diagnostic values are used to determine *diagnostic* or *distinctive* manifestations of cGVHD (Table 84.1 and Figures 84.5–84.21). A color atlas and classification of important cGVHD manifestations is available at http://www.asbmt.org/?page=MeasureCGVHD. Features that are neither diagnostic nor distinctive cannot be used to establish a diagnosis of cGVHD because they are either *common* to acute and chronic GVHD, or else represent *other features* that also lack specificity for cGVHD. Therefore, a diagnosis of cGVHD first requires the distinction from acute GVHD as recognized by the presence of one or more of erythema, maculopapular rash, pruritus, or acute involvement of the GI tract or liver. The second requirement is the presence of at least one diagnostic manifestation (i.e. found only in cGVHD) or at least one distinctive manifestation that is highly suggestive of cGVHD and confirmed by pertinent biopsy or other relevant tests (Table 84.1).

Lastly, other possible diagnoses that could account for the manifestations in question (e.g. infection, drug effect, others) should be excluded. For example, the oral lesions of candidiasis, herpes simplex or human papilloma virus, and squamous cell carcinoma always need to be considered.

Histological confirmation is necessary in the absence of diagnostic clinical features, or distinctive features that are unable to be confirmed by other pertinent tests [e.g. bronchiolitis obliterans based on pulmonary function and high-resolution chest computed tomography (CT) scan].

Table 84.1 Classification of manifestations for the clinical diagnosis of cGVHD

Organ or site	Diagnostic (sufficient to establish a chronic GVHD diagnosis)	Distinctive (insufficient alone to establish a chronic GVHD diagnosis)	Common (seen with both acute and chronic GVHD)
Skin	Poikiloderma Lichen planus-like Sclerotic Morphea-like Lichen sclerosis-like	Depigmentation Papulosquamous lesions	Erythema Maculopapular Pruritus
Nails		Dystrophy Longitudinal ridging, splitting or brittleness Onycholysis Pterygium ungus Nail loss (usually symmetric and affects most nails)	
Scalp and body hair		New alopecia not due to chemoradiotherapy Scaling	
Mouth	Lichenoid Hyperkeratotic plaques Diminished oral cavity opening from sclerosis	Xerostomia Mucocele Mucosal atrophy Pseuodmembranes[a] Ulcers[a]	Gingivitis Mucositis Erythema Pain
Eyes		New onset of sicca (dryness, gritty, or painful[b]) Cicatricial conjunctivitis Keratoconjunctivitis sicca[b] Confluent areas of punctate keratopathy	
Genitalia	Lichen planus-like or lichen sclerosis-like Females: Vaginal scarring or genital agglutination Males: Phimosis or urethral scarring	Erosions[a] Fissures[a] Ulcers[a]	
GI tract	Esophageal web Esophageal strictures or stenosis in upper to mid third[a]		Anorexia, nausea, vomiting, diarrhea Failure to thrive/weight loss
Liver[c]			Bilirubin >2 × ULN[a] Alkaline phosphatase >2 × ULN[a] ALT >2 × ULN[a]
Lung	Bronchiolitis obliterans)[d] (biopsy confirmed)	Bronchiolitis obliterans)[d] (based on PFTs and CT scan imaging)	
Muscles, fascia, joints	Fasciitis Joint stiffness or sclerotic contractures	Myositis or polymyositis[b]	

Manifestations acknowledged as cGVHD if the diagnosis is already confirmed

Skin	Sweat impairment, ichthyosis, keratosis pilaris, hypopigmentation, hyperpigmentation
Hair	Thinning scalp hair not otherwise explained (typically patchy, coarse, or dull), premature graying, or alopecia not explained by endocrine or other causes
Eyes	Photophobia, periorbital hyperpigmentation, blepharitis (eyelid erythema with edema)
GI tract	Exocrine pancreatic insufficiency
Muscles/joints	Edema, muscle cramps, arthralgia, or arthritis
Hematology	Thrombocytopenia, eosinophilia, lymphopenia
Immune	Hypo- or hypergammaglobulinemia, autoantibodies (AIHA, ITP), Raynaud's phenomenon
Lung	Cryptogenic organizing pneumonia (COP/BOOP)
Other	Hypo- or hypergammaglobulinemia, autoantibodies (AIHA, ITP) Ascites, pericardial or pleural effusions, peripheral neuropathy, nephrotic syndrome, myasthenia gravis, cardiac conduction abnormality, cardiomyopathy

AIHA, autoimmune hemolytic anemia; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BOOP, bronchiolitis obliterans with organizing pneumonia; COP, cryptogenic organizing pneumonia; CT, computed tomography; ITP, immune thrombocytopenia; PFTs, pulmonary function tests; ULN, upper limit or normal.

[a] In all cases, infection, drug effects, malignancy, and other cause must be excluded.

[b] Diagnosis of cGVHD requires biopsy or radiographic confirmation (or Schirmer test or slit lamp examination for eyes).

[c] Because liver histology in acute and chronic GVHD is not distinguishable, the diagnosis of cGVHD cannot be made on the basis of biopsy alone and requires a distinctive manifestation in at least one other organ system.

[d] Criteria for diagnosing bronchiolitis obliterans: forced expiratory volume in 1 s/forced (or slow) vital capacity ratio <0.7 *and* forced expiratory volume in 1 s <75% of predicted *and* evidence of air trapping or small airway thickening or bronchiectasis on high-resolution chest CT (with inspiratory and expiratory images), *or* residual volume >120%.

Organs in which the diagnosis may not be straightforward

Gastrointestinal tract

Diagnostic features include *esophageal web*, *stricture*, or *concentric rings* that may present as progressive dysphagia and require documentation by endoscopy or barium contrast radiograph. The classical "wasting syndrome" of untreated cGVHD is now uncommon with current immunosuppressive therapy. When diarrhea and weight loss, with or without abdominal cramping, occur late after HCT, it is usually unclear whether these represent cGVHD, infection, medication toxicity, or, infrequently, exocrine pancreatic insufficiency, which is recognized as a manifestation of cGVHD provided that the diagnosis of cGVHD has otherwise been established. The temporal relationship between symptoms and the addition or tapering of immunosuppressive medications could favor, respectively, opportunistic infection or a flare of GVHD. Common offending medications include high-dose oral magnesium, mycophenolate mofetil, and narcotic-associated pseudo-obstruction. Antibiotic therapy may predispose to *Clostridium difficile* toxin enteritis that should always be excluded by enteric screening for this and other viral, protozoan, and bacterial pathogens. If the history suggests steatorrhea and the diagnosis remains unclear, it may be useful to screen for exocrine pancreatic insufficiency by microscopy of a Sudan-stained spot fecal specimen or by fat quantitation in a 72-hour stool collection. Because stool tests have limited sensitivity for detecting milder cases of pancreatic insufficiency, a trial of pancreatic enzyme therapy is reasonable and may be diagnostic. Fat-soluble

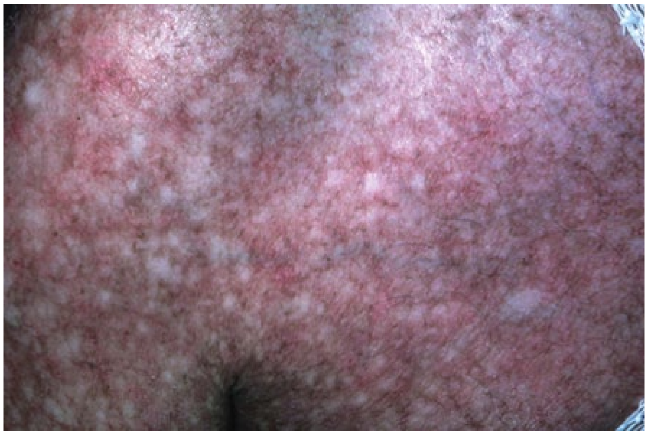

Figure 84.5 Poikiloderma, a diagnostic manifestation of cGVHD, which includes both atrophic and pigmentary changes. Note the combination of reticulated pattern, epidermal atrophy (cigarette-paper wrinkling of the skin surface), erythema, and brown pigment forming the borders of skin-colored or depigmented skin. (For a color version of this figure, please see the color plate section.)

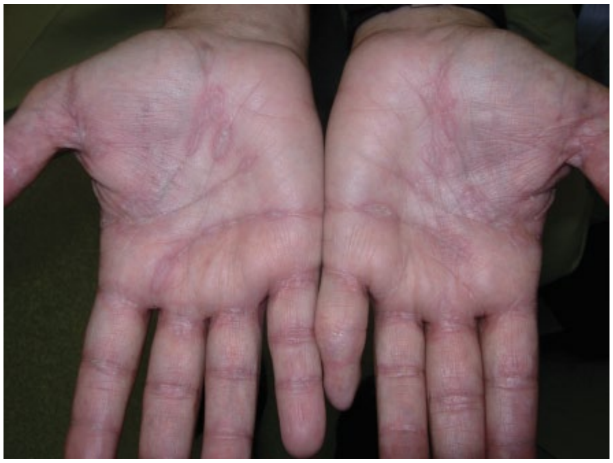

Figure 84.6 Lichen planus-like eruption involving the palmar surfaces, a diagnostic manifestation of cGVHD. Note the erythematous/violaceous flat-topped papules or plaques with or without surface reticulations or a silvery or shiny appearance on direct light. (For a color version of this figure, please see the color plate section.)

vitamin A, D, and E levels are low in severe cases, and replacement using water-soluble formulations may be necessary. Pancreatic insufficiency may be reversible after cGVHD has become inactive [48]. Lactose intolerance may be associated with intestinal GVHD and lactose avoidance or a trial of chewable lactase tablets with dairy products may be helpful if diarrhea consistently occurs with dairy products.

Lungs

The only diagnostic manifestation of lung cGVHD is biopsy-proven bronchiolitis obliterans (BO) (Figure 84.19). BO that is diagnosed clinically by pulmonary function and radiologic testing requires at least one other distinctive manifestation in a separate organ system to establish the initial diagnosis of cGVHD [2]. Patients with BO may be asymptomatic early in the disease process but frequently develop dyspnea, cough, or wheezing as they develop significant airflow obstruction. Pneumothorax, pneumomediastinum, and subcutaneous emphysema may be seen in advanced disease. BO is clinically diagnosed when all of the following criteria are met: forced expiratory volume in 1 s/forced vital capacity ratio <0.7 [or forced expiratory volume in 1 s (FEV_1)/slow vital capacity <0.7], *and* FEV_1 <75% of predicted with ≥10% decline over less than 2 years *and* evidence of air trapping or small airway thickening or bronchiectasis on high-resolution chest CT (with inspiratory and expiratory images), or residual volume >120%. The BO diagnosis also requires exclusion

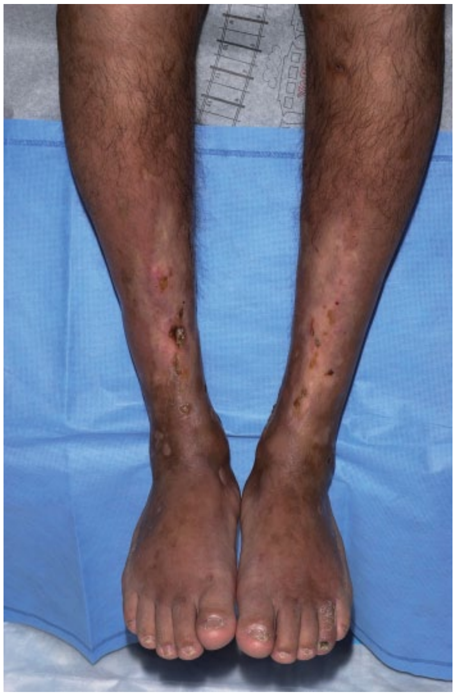

Figure 84.7 Diffuse deep sclerotic features involving the lower extremities, a diagnostic feature of cGVHD. Note the non-movable/hidebound subcutaneous tissues, erosions, and ulcerations, loss of hair follicles, and toenail dystrophy. (For a color version of this figure, please see the color plate section.)

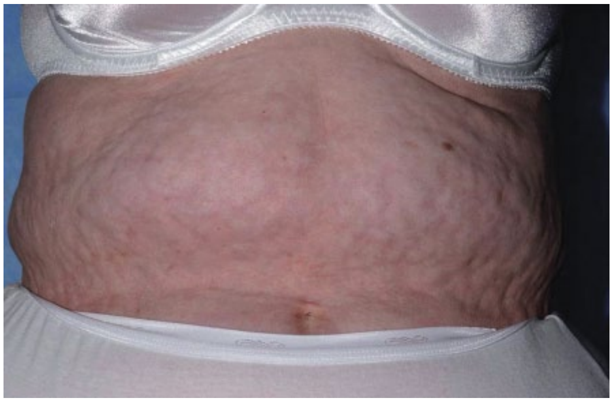

Figure 84.8 Alternative manifestation of deep sclerosis common in areas of excess subcutaneous tissue such as the abdomen, upper arms, and buttocks. Tissue is not hidebound but demonstrates prominent rippling, dimpling, or a cellulite-like appearance. (For a color version of this figure, please see the color plate section.)

of respiratory tract infection, and radiographic infiltrates should be evaluated by upper respiratory tract viral screen, consideration of sinus infection, sputum culture, and bronchoalveolar lavage. Restrictive pulmonary function test (PFT) abnormalities may be related to sclerosis of the chest wall or myopathy related to glucocorticoid therapy and other causes. Cryptogenic organizing pneumonia (COP) is most often associated with restrictive pattern PFT, but PFT results may show a normal pattern when the infiltrates are small (unifocal) (Table 84.2). COP may be due to GVHD or other causes but can be acknowledged as part of the cGVHD manifestations if cGVHD diagnosis is already confirmed. The diagnosis requires at least a bronchoalveolar lavage to exclude bacterial, viral, fungal, and other opportunistic pathogens; lung biopsy may also be required for diagnosis and to guide treatment. Therapy and prognosis of COP are different from those of BO, in that COP usually responds quickly to high-dose glucocorticoid therapy and is often reversible, whereas moderate or severe BO is generally irreversible and with variable response to corticosteroids.

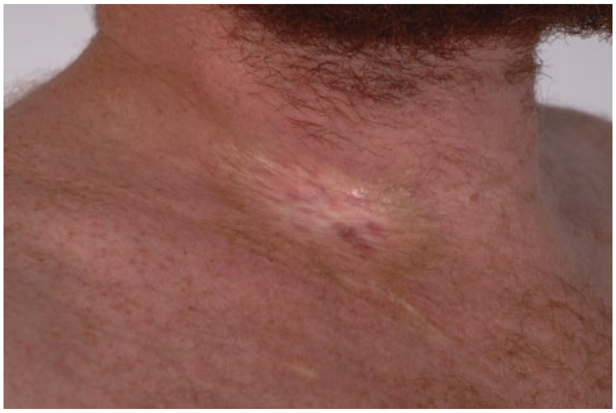

Figure 84.9 Morphea-like superficial sclerotic skin changes, a diagnostic feature of cGVHD. Note the localized, patchy areas of movable smooth or shiny skin with a leathery-like consistency, often with dyspigmentation. In this picture, there is a fibrotic, hypopigmented area in the center of the plaque with a slightly hyperpigmented border. (For a color version of this figure, please see the color plate section.)

Musculoskeletal system

Diagnostic features include fascial involvement often associated with sclerosis of the overlying skin and subcutaneous tissue (Figure 84.21). Fascial involvement may develop without overlying sclerotic changes of the skin and initially manifest as joint stiffness or skin dimpling when present near joints or as unilateral or bilateral extremity edema. Fasciitis is detected on examination by stiffness, restricted range of motion associated with joint contractures (Figure 84.22). Clinical myositis that is characterized by tender muscles or severe proximal weakness is a distinctive but non-diagnostic manifestation of cGVHD that is supported by the presence of elevated serum creatinine phosphokinase or aldolase, and sometimes with electromyographic findings. The differential diagnosis should consider the myopathy that may occur in patients taking statins, especially at higher doses when combined with calcineurin inhibitor therapy or sirolimus. Proximal myopathy is more commonly associated with corticosteroid therapy especially when tapering steroids. Muscle cramps are a common problem in patients with cGVHD even when serum electrolytes are normal. Arthralgia and arthritis are uncommon and are occasionally associated with the presence of autoantibodies.

Hematopoietic and immune systems

Hematopoietic abnormalities are common in cGVHD but also nonspecific and are not used to establish its diagnosis.. Thrombocytopenia ($<100 \times 10^9$/L), lymphopenia ($\leq 0.5 \times 10^9$/L), eosinophilia ($\geq 0.5 \times 10^9$/L), hypogammaglobulinemia, or hypergammaglobulinemia may be present. Autoantibodies may develop with autoimmune hemolytic anemia and immune thrombocytopenic purpura. Thrombocytopenia ($<100 \times 10^9$/L) at the initial diagnosis of cGVHD is a risk factor for NRM. Lymphopenia has been reported as a risk factor both for survival in cGVHD and for development of GVHD after DLI [49,50]. In the absence of other cGVHD manifestations and other causes, cytopenias may reflect an immune-mediated process and a trial of glucocorticoid or other immunosuppressive therapy may be of diagnostic and therapeutic value.

Renal

Two large retrospective studies have reported cumulative incidences of GVHD-associated nephrotic syndrome (NS) of 6.1% and 8%, suggesting that this manifestation may be more

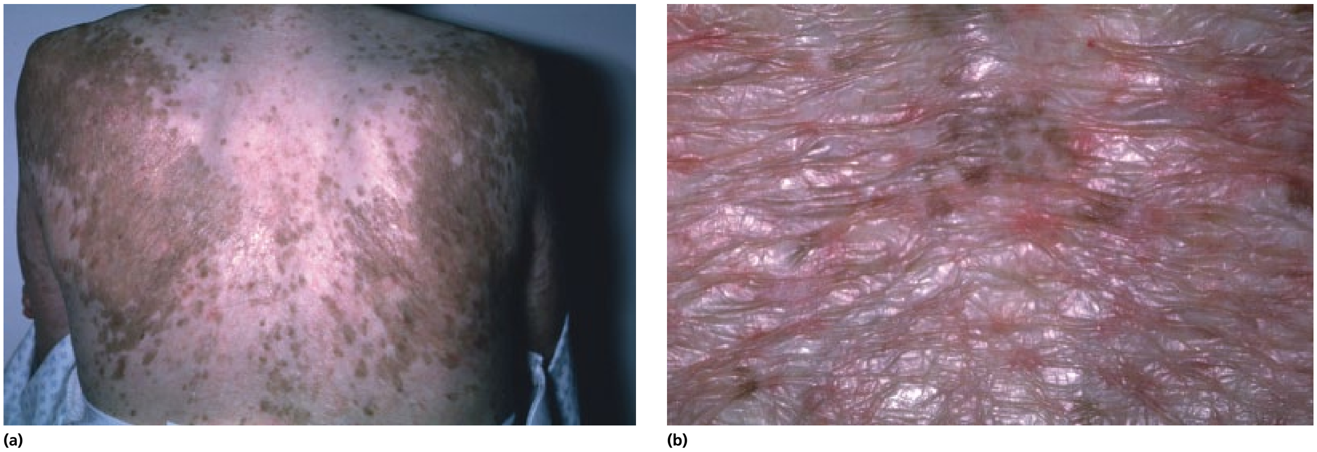

Figure 84.10 Lichen sclerosis-like lesion, a diagnostic manifestation of cGVHD. Note the discrete to coalescent gray to white movable papules or plaques, with a shiny appearance and leathery consistency (a) or cigarette paper-like textural changes (b). (For a color version of this figure, please see the color plate section.)

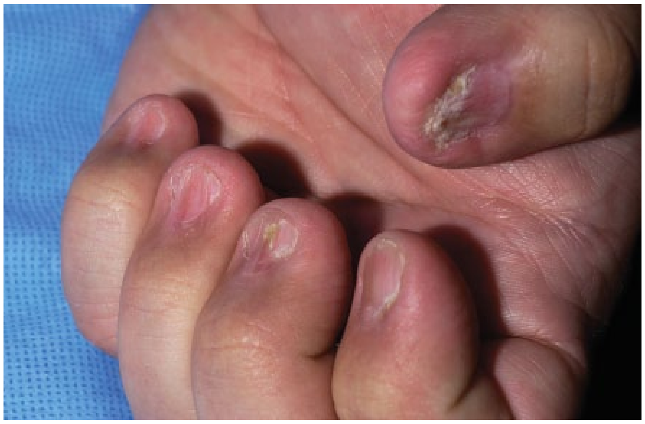

Figure 84.11 Nail dystrophy involving multiple digits is a distinctive feature of cGVHD, although it is insufficient alone to establish the diagnosis . Note the longitudinal ridging, splitting, and brittle nail features, and also periungual erythema. (For a color version of this figure, please see the color plate section.)

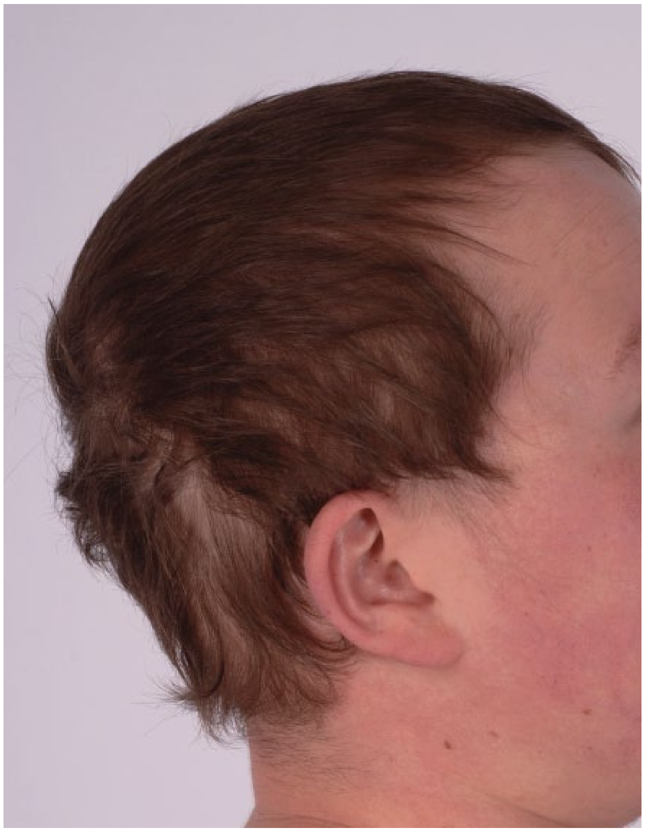

Figure 84.12 New onset of patchy alopecia after recovery from chemoradiotherapy is another distinctive manifestation of cGVHD (but is insufficient alone to establish the diagnosis). Patchy alopecia may involve loss of scalp or body hair. (For a color version of this figure, please see the color plate section.)

frequently encountered than previously thought. The first study found that all patients with NS had received RIC, whereas patients receiving high-dose conditioning at the same institution during the same period had no reported cases of NS. Patients who developed NS suffered significant morbidity, including

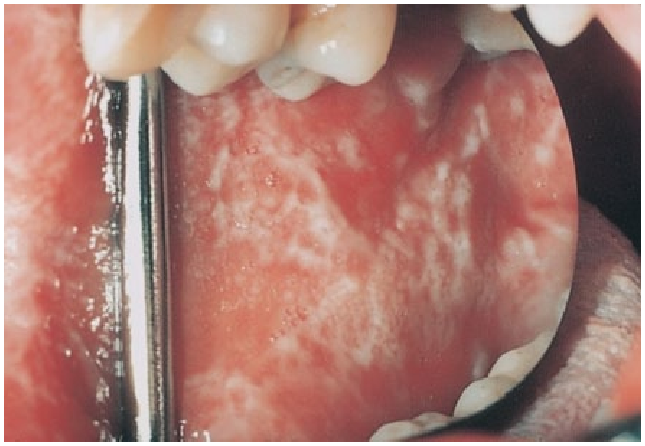

Figure 84.13 Lichenoid lesions of oral cGVHD showing crythema, white striae, plaque, and ulcer formation, day 394. (For a color version of this figure, please see the color plate section.)

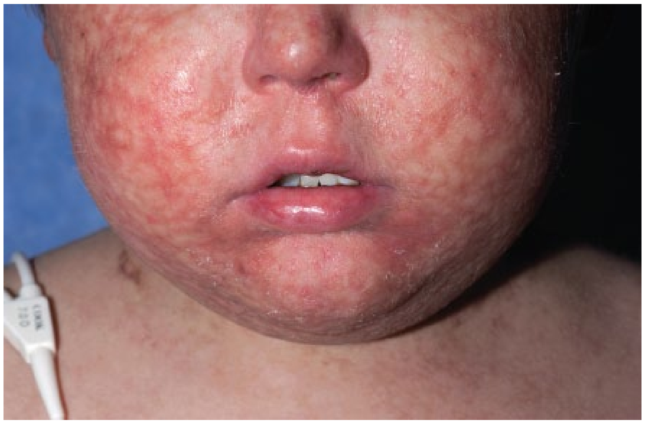

Figure 84.14 Decreased oral range of motion and microstomia in a patient with sclerotic features of cGVHD. This is a diagnostic manifestation. Note the erythema, edema, and atrophy of the vermillion lip and labial mucosa. (For a color version of this figure, please see the color plate section.)

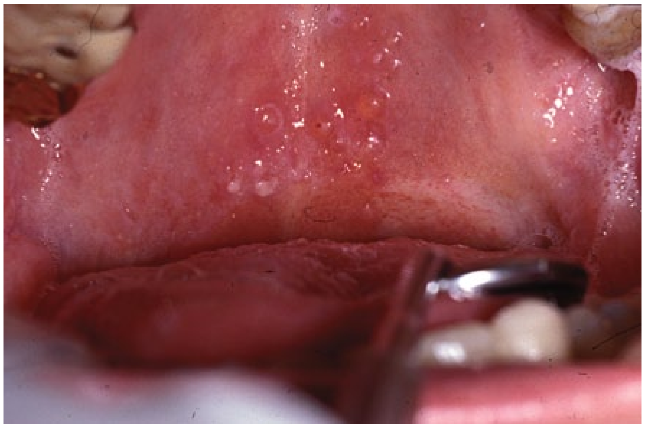

Figure 84.15 Numerous vesicle-like mucoceles (a distinct manifestation of cGVHD) are seen along the center of the soft palate. Patchy white lichenoid hyperkeratosis (diagnostic of cGVHD) and interspersed moderate erythematous changes are also evident across the soft palate. Additionally, note the foamy mucus saliva consistent with GVHD salivary gland dysfunction. (For a color version of this figure, please see the color plate section.)

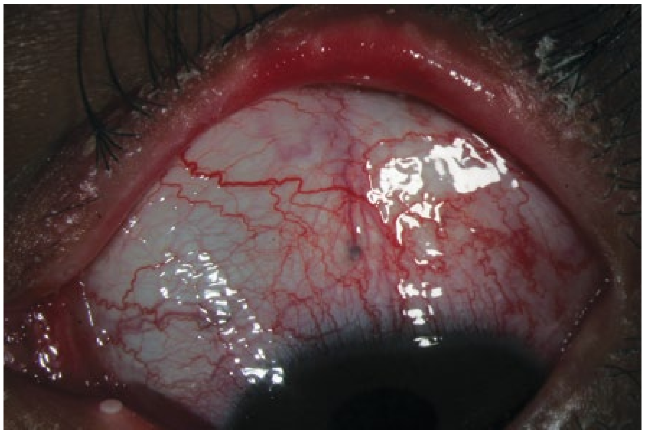

Figure 84.16 Keratoconjunctivitis sicca with blepharitis. The eyelid margins are thickened, edematous, and erythematous. Also note plugging of the meibomian gland orifices (along the eyelid margin) and significant conjunctival hyperemia/injection. A punctal plug can be seen at the lower left margin of the image. (For a color version of this figure, please see the color plate section.)

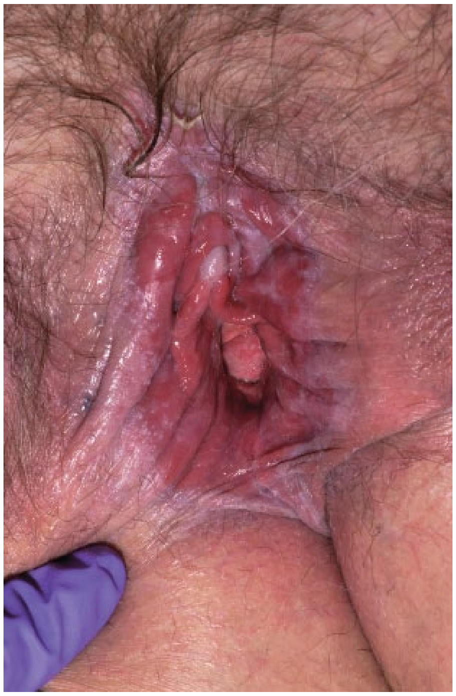

Figure 84.17 cGVHD involving the vulvovaginal tissues. Note lichen planus-like manifestations, which are diagnostic of cGVHD. Also seen are erythema and agglutination of the labial tissues. (For a color version of this figure, please see the color plate section.)

thromboembolic complications and progressive renal failure, and were unlikely to respond to immunosuppression [51]. The second study found no differences between conditioning regimens, but rather observed an association with hematopoietic cell source with increased probability of NS in patients receiving peripheral blood stem cells (PBSCs) versus bone marrow. All patients in this study responded to immunosuppressive therapy [52]. See also Chapter 96.

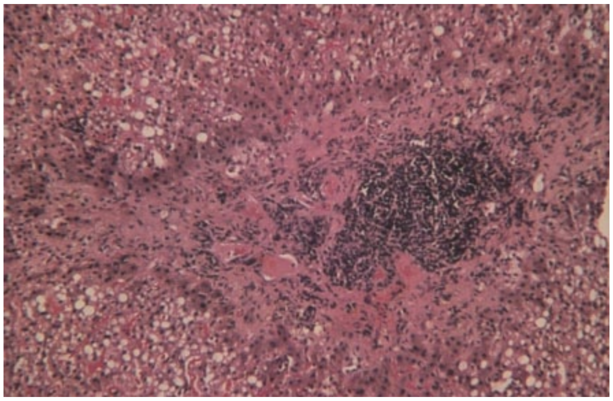

Figure 84.18 cGVHD of the liver, day 166. This biopsy shows a prominent plasmacytic infiltrate in the portal area and a paucity of interlobular bile ducts. The histological dichotomy between acute GVHD and cGVHD is less clear in the liver than in skin. However, increased portal inflammation and loss of bile ducts are more common in cGVHD. Despite the frequency of chronic hepatic GVHD, cirrhosis and liver failure are rare and may reflect superinfection with hepatitis C virus. (See also Chapter 23.) (For a color version of this figure, please see the color plate section.)

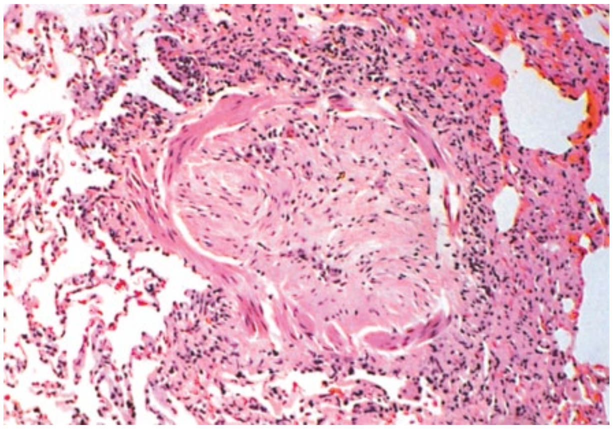

Figure 84.19 Bronchiolitis obliterans in a lung biopsy, day 396. The patient had cGVHD with severe obstructive pulmonary disease. Similar small airway inflammation with fibrosis is seen in lung allograft rejection. (See also Chapter 23 and Chapter 47.) (For a color version of this figure, please see the color plate section.)

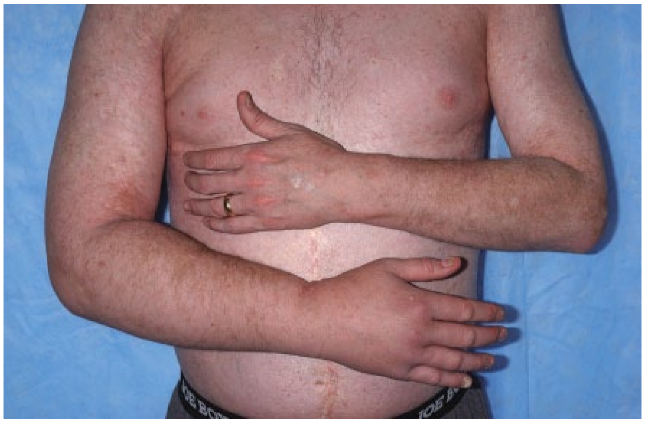

Figure 84.20 Edema in the extremities can be bilateral or, as shown, unilateral. Edema may be an early sign of evolving subcutaneous sclerosis and fasciitis. (For a color version of this figure, please see the color plate section.)

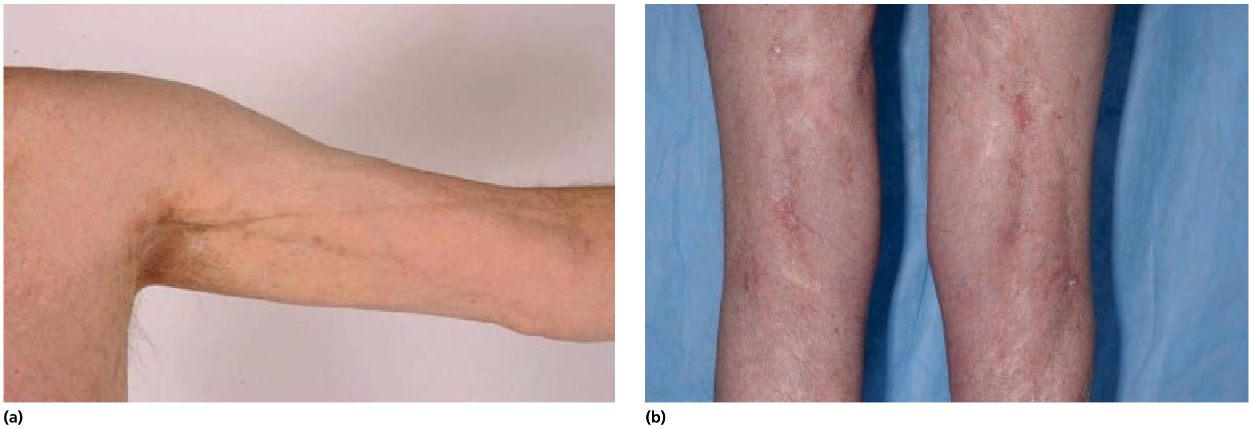

Figure 84.21 Manifestations suggestive of fascial involvement by cGVHD (a diagnostic feature) can include rippling or the groove sign. (For a color version of this figure, please see the color plate section.)

Table 84.2 Distinguishing bronchiolitis obliterans (BO) from cryptogenic organizing pneumonia (COP)

Feature	BO	COP
Symptoms	Dyspnea, cough, wheeze, or asymptomatic (early stages)	Fever, dry cough, dyspnea
Signs	Wheeze, crackles, or none	Crackles, tachypnea, or none
High-resolution CT scan	Air trapping with expiratory images, small airway thickening, bronchiectasis (advanced)	Infiltrates present, either focal or multifocal (but not diffuse)
FEV$_1$	<75% predicted with ≥10% decline over <2 years	Reduced or normal
FEV$_1$/FVC (or SVC)	<0.70	Normal
Residual volume	>120%	Reduced or normal
Response to steroids	Usually do not recover FEV$_1$ after steroid therapy	Often recover FEV$_1$ and FVC after high-dose steroid therapy but relapses do occur
Pulmonary prognosis	Poor	Good
Survival	Relatively poor	Relatively good

FEV$_1$, forced expiratory volume in 1 s; FVC, forced vital capacity; SVC, slow vital capacity.

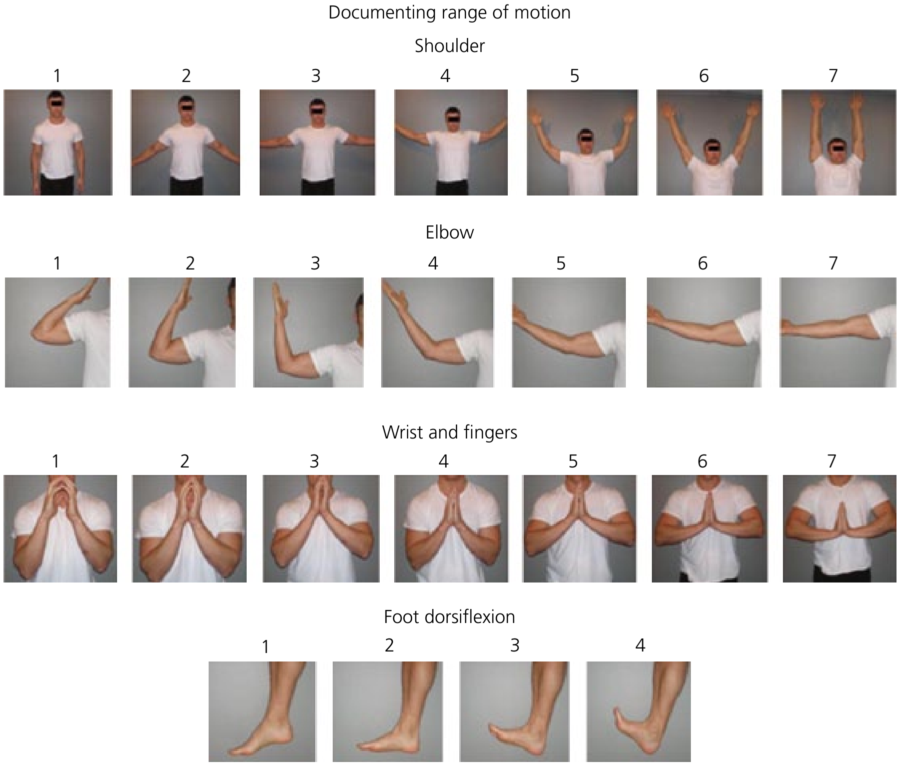

Figure 84.22 Documenting range of motion. Beginning with the full (normal) range of motion on the right, the images indicate progressively more limited range of motion as the numeric scores decrease toward maximally restricted joint motion. By row, from top to bottom, the tasks being attempted are full shoulder abduction with upper arms brought next to ears, full elbow extension with arms outstretched, "Buddha prayer" position, and full ankle dorsiflexion. Source: Carpenter 2011 [84]. Reproduced with permission of the American Society of Hematology.

Other manifestations

Serositis (pericardial and pleural effusions or ascites), peripheral neuropathy, myasthenia gravis, and cardiac function abnormalities occur rarely in cGVHD but are all diagnoses of exclusion unless the patient has additional features of cGVHD.

Organ severity staging of cGVHD

Historically, cGVHD was classified as limited (localized skin involvement and or liver dysfunction) or extensive (generalized skin involvement, liver histology showing aggressive hepatitis or involvement of any other target organ) [1]. This system has been replaced by NIH global severity grading (none, mild, moderate, severe), which in turn uses a 0–3 point scoring of cGVHD severity within each affected organ or site, taking functional impact into account (Figure 84.4b) [2]. The eight scored organs include skin, mouth, eyes, GI tract, liver, lungs, joints and fascia, and female genital tract. Before the 2014 NIH cGVHD Consensus, scoring did not consider whether the organ-specific manifestation was attributed to cGVHD versus another cause (e.g. diarrhea associated with magnesium therapy or *C. difficile* toxin). This point is emphasized by the ~60% incidence of lung involvement reported in the recent Chronic GVHD Consortium study that is out of keeping with the 10–15% incidence of BO found in earlier reports (Figure 85.4a and b). A score of 1 means that there is no significant impairment of function or activities of daily living (ADL), a score of 2 means impairment of ADL without major disability and a score of 3 indicates impairment of ADL with major disability. Scoring can be easily conducted in the clinic and the only mandated laboratory tests for its completion are liver function tests (Table 84.3).

The pulmonary NIH score uses symptoms plus the results of PFTs whenever possible, although evaluation can also be accomplished by simply assessing dyspnea symptoms and need for supplemental oxygen. When discrepancies exist between scores based on lung symptoms versus PFTs, the FEV$_1$ score should be used (Table 84.3). The diagnosis and scoring of bronchiolitis obliterans has been recently revised by the NIH 2014 cGVHD Consensus [13]. To increase the specificity of the cGVHD lung function score (LFS) for obstructive lung defects this score no longer includes the carbon monoxide diffusing capacity (DLCO) and just includes the FEV$_1$.

Table 84.3 NIH cGVHD 0–3 scale for scoring severity in each organ

	Score 0	Score 1	Score 2	Score 3
PERFORMANCE SCORE: KPS/ECOG/LPS	Asymptomatic and fully active (ECOG 0; KPS **OR** LPS 100%)	Symptomatic, fully ambulatory, restricted only in physically strenuous activity (ECOG 1, KPS **OR** LPS 80–90%)	Symptomatic, ambulatory, capable of self-care, >50% or waking hours out of bed (ECOG 2, KPS **OR** LPS 60–70%)	Symptomatic, limited self-care, >50% of waking hours in bed (ECOG 3–4, KPS **OR** LPS <60%)
SKIN Diagnostic/distinctive features ☐Present ☐Absent %BSA____	No manifestations	<18% BSA with disease signs but **NO** sclerotic features	19–50% BSA **OR** with superficial sclerotic features "not hidebound" (able to pinch)	>50% BSA **OR** deep sclerotic features "hidebound" (unable to pinch) **OR** impaired mobility, ulceration or severe pruritus
MOUTH Diagnostic/ distinctive features ☐Present ☐Absent	No symptoms	Mild symptoms with disease signs but not limiting oral intake significantly	Moderate symptoms with disease signs **WITH** partial limitation or oral intake	Severe symptoms with disease signs on examination **WITH** major limitation or oral intake
EYES	No symptoms	Mild dry eye symptoms not affecting ADL (requiring eyedrops <3× per day) **OR** asymptomatic signs of keratoconjunctivitis sicca	Moderate dry eye symptoms partially affecting ADL (requiring eyedrops >3× per day or punctal plugs) **WITHOUT** vision impairment	Severe dry eye symptoms significantly affecting ADL (special eyewear to relieve pain) **OR** loss of vision caused by keratoconjunctivitis sicca
GI TRACT	No manifestations	Manifestations such as nausea, vomiting, anorexia, dysphagia, abdominal pain or diarrhea **WITHOUT** significant weight loss	Manifestations associated with mild-to-moderate weight loss (5–15%)	Manifestations associated with significant weight loss (>15%), requires nutritional supplement for most calorie needs **OR** esophageal dilatation
LIVER	Normal LFTs	Elevated bilirubin, AP, AST or ALT <2 × ULN	Elevated bilirubin >3 mg/day or bilirubin, enzymes 2–5 × ULN	Bilirubin or enzymes >5 × ULN
LUNGS Pulmonary function test results **FEV$_1$** **DLCO**	No symptoms FEV$_1$ ≥80%	Mild symptoms (dyspnea climbing one flight of stairs) FEV$_1$ 60–79%	Moderate symptoms (dyspnea walking on flat ground) FEV$_1$ 40–59%	Severe symptoms (dyspnea at rest; requiring O$_2$) FEV$_1$ ≤39%
JOINTS/FASCIA	No manifestations	Mild tightness of arms or legs, normal or mild decreased range of motion (ROM) **AND** not affecting ADL	Tightness of arms or legs, **OR** joint contractures, erythema thought due to fasciitis, moderate decrease ROM **AND** mild to moderate limitation of ADL	Contractures **WITH** significant limitation of ROM **AND** significant limitation of ADL (unable to tie shoes, button shirts, dress self, etc.)
GENITAL TRACT Diagnostic/ distinctive features ☐Present ☐Absent ☐Not examined	No symptoms	Symptomatic with mild signs on exam **AND** no effect on coitus and minimal discomfort with gynecologic exam	Symptomatic with moderate signs on exam **AND** with mild dsypareunia or discomfort with gynecologic exam	Symptomatic **WITH** advanced signs (stricture, labial agglutination, or severe ulceration) **AND** severe pain with coitus or inability to insert a vaginal speculum

Abbreviations: ADL, activities of daily living, ALT, alanine aminotransferase; AP, alkaline phosphatase; AST, aspartate aminotransferase; BSA, body surface area; ECOG, Eastern Cooperative Oncology Group; KPS, Karnofsky Performance Status; LPS, Lansky Performance Status; LFS, lung function score; LFTs, liver function tests; ULN, upper limit or normal.

Global severity staging of cGVHD

The NIH cGVHD global severity score (none, mild, moderate, severe) is derived by combining organ-specific scores and has replaced the historical "limited" and "extensive" categories. Global scoring aligns better with patient and physician estimates of cGVHD severity [2]. Global scoring has treatment implications and considers the number of organs involved, the degree of involvement in affected organs/sites, and, importantly, the presence of mild or moderate lung involvement will upgrade global scores by one point (Table 84.4). The easily accomplished individual organ severity and global severity staging is considered useful for baseline or sentinel time points in the course of the cGVHD therapy in clinical practice or in clinical trials.

Although not initially intended for response monitoring in cGVHD intervention trials, emerging data from the Chronic GVHD Consortium suggest that NIH organ severity scoring (skin, oral, ocular, and joints) and global scores perform best in terms of predicting patient- and physician-perceived improvement or worsening over time and may also predict other key transplant outcomes such as NRM [4,8–10].

Histopathology and diagnosis of cGVHD

cGVHD is a clinical diagnosis. However, histological confirmation has an important role in the final assessment. Biopsies may be useful for establishing a diagnosis of cGVHD when no diagnostic manifestations of cGVHD are present, when alternative diagnoses are being entertained, or clinical assessment is difficult because of concomitant medical conditions. Among cGVHD referrals to the Johns Hopkins University, 7% of patients who did not have biopsies prior to referral and before starting cGVHD therapy had other diagnoses [53]. Specific details about the histopathology of cGVHD are covered in Chapter 26.

Management of cGVHD

Prevention

As in acute GVHD, preventive approaches have remained a desirable goal. Whereas the prevention of cGVHD provides obvious benefit in the transplantation of non-malignant diseases, the same cannot be said for malignant diseases because effective but non-targeted prevention may significantly abrogate crucial graft-versus-tumor (GVT) effects.

Among the aforementioned risk factors for developing cGVHD or prolonging its therapy, there are few modifiable factors such as choosing better matched donors, avoiding female donors for male recipients, and using marrow or cord blood rather than peripheral blood as a source of hematopoietic cells. However, these modifications have limited impact on cGVHD and more effective methods of prevention are needed. Although acute GVHD is the best predictor for developing cGVHD, strategies that have reduced acute GVHD rates have not reliably reduced the rates of cGVHD [20,54–56]. Other unsuccessful attempts to prevent cGVHD include addition of hydroxychloroquine, thalidomide, intravenous immunoglobulin, or preemptive treatment of subclinical cGVHD found in skin and lip biopsies [57–60]. Graft manipulation by T-cell depletion is successful in reducing acute GVHD but the effects on cGVHD are less evident and may depend on graft manipulation methods or source of stem cells [20,21].

Table 84.4 Indications for systemic therapy according to severity and high-risk features of cGVHD

Category	Maximum severity in all organs (scores according to Table 87.2)	No. of organs	High-risk feature[a]	Systemic treatment
Mild	1 (0 for lung)	≤2	Absent	No
Moderate (a)	1 (0 for lung)	≥3	Present	Yes[b]
Moderate (b)	2 (1 for lung)	Any	Present or absent	Yes[b]
Severe	3 (2 for lung)	Any	Present or absent	No

[a] High risk defined as thrombocytopenia (<100 × 10^9/L) or receiving glucocorticoids >0.5 mg/kg/day at the onset of cGVHD.

[b] The benefit of graft-versus-leukemia/tumor effect versus the risk of delaying systemic treatment for cGVHD needs to be weighted based on the risk of recurrent malignancy after transplantation.

A few promising approaches require further validation by other groups. The first approach was the randomized phase III trial conducted in Europe that compared standard GVHD prophylaxis in adults with or without pre-transplantation ATG-Fresenius. With follow-up now extended to 3 years, the cumulative incidence of extensive cGVHD was 12.2% in the ATG-Fresenius group versus 45% in the control group ($p < 0.0001$). A non-significant reduction in NRM without increased relapse risk led to an overall survival rate of 55% in the ATG-Fresenius group versus 43% in the control group [hazard ratio (HR) 0.84, $p = 0.39$] but the 3-year probability of survival free of immunosuppressive therapy was 53% versus 17%, respectively [61]. Two other approaches that are being compared in a randomized phase III trial (BMT CTN 1101] arose from the promising results of parallel phase II BMT CTN trials of double unrelated cord blood transplantation and non-T-cell-depleted haploidentical marrow transplantation with RIC and post-transplant cyclophosphamide. Although direct comparisons should not be made, cGVHD rates at 1 year were low: 13% after haploidentical BMT and 25% after double cord blood transplant [62]. The major obstacle to optimizing cGVHD prevention approaches remains our rudimentary understanding of cGVHD biology. The field has prioritized relevant correlative biology studies in an effort to generate this critically needed information.

Treatment

Therapy of cGVHD depends heavily on a coordinated multidisciplinary team that often includes transplantation specialists, a primary healthcare provider, organ-specific consultants, nurses, and ancillary services such as social services, vocational specialists, and patient and family support groups and systems. Principal components of cGVHD therapy include systemic immunosuppressive medications for an average of 2–3 years, integrated with ancillary therapy and supportive care. Ultimately, about 85% of patients who survive beyond 5 years after diagnosis are able to discontinue systemic therapy [27]. The goal of cGVHD therapy is to stop destructive immune dysregulation, alleviate symptoms, and prevent disease progression that may lead to irreversible disability or death. The ultimate goal is to establish tolerance and withdraw immunosuppressive therapy. It is also important to recognize that even after permanent withdrawal of immunosuppression, patients remain at increased risk for late complications of allogeneic HCT and require continued monitoring by providers familiar with the late effects of HCT and cancer therapy [63,64].

Primary systemic therapy

The need for cGVHD therapy may be guided by the NIH global severity score and the presence or absence of high-risk features for NRM (Table 84.4). For example, mild but symptomatic cGVHD of the skin and or mouth is often effectively treated with local therapies alone (e.g. topical steroids to the skin or steroid mouth rinses), yet these same features in a patient whose platelet count is <100 × 10^9/L at the time cGVHD is diagnosed would justify the addition of systemic therapy. However, systemic therapy should always be considered for patients with moderate or severe global severity. Good medical practice and judgment dictate flexibility in this recommendation and the underlying reason for transplantation (e.g. high-risk malignancy versus non-malignant disease) or current comorbid conditions (e.g. infection) into decisions on whether or not to treat with systemic immunosuppression.

To date, only six randomized phase III trials have ever been reported for initial therapy of cGVHD [65–70]. None of these studies demonstrated any benefit of additional agents (azathioprine, cyclosporine, thalidomide, mycophenolate mofetil, or hydroxychloroquine) over prednisone alone, except for lower rates of avascular necrosis when cyclosporine was added (13% versus 22%, $p = 0.04$). Hence the most widely used initial approach is cyclosporine or tacrolimus and prednisone initially at 1 mg/kg once daily [71,72]. Cyclosporine or tacrolimus is dosed twice daily to keep levels therapeutic. The starting prednisone dose has some flexibility, generally balancing cGVHD severity against the relative individual contraindications for high-dose prednisone. It is important to avoid split daily dose regimens for prolonged prednisone therapy, and once the patient is responding or showing signs of stable disease, generally after 2 weeks, prednisone is tapered to an alternate-day schedule over 4 weeks (Table 84.5) which avoids or minimizes many steroid-related complications [73]. Responses are evaluated at least every 3 months after alternate-day dosing is achieved, and after all reversible manifestations have resolved prednisone is gradually tapered by 10% every 2–4 weeks as tolerated. Examples of potentially irreversible manifestations include severe ocular sicca, joint contractures, and BO.

It is worth detailing further the results of the non-blinded phase III trial that compared prednisone alone with prednisone plus cyclosporine in 287 patients with standard-risk cGVHD without thrombocytopenia. Importantly, the cumulative incidence of NRM, overall survival, relapse, need for secondary cGVHD therapy, and discontinuation of immunosuppressive medications were not significantly different between the two arms [67]. However, survival without recurrent malignancy was better in the prednisone-only arm (71% versus 61%, $p = 0.03$). Hence there is no evidence that initial combination therapy of cyclosporine with prednisone improves control of cGVHD in standard-risk patients with platelet counts >100 × 10^9/L. The reason why combination therapy with prednisone and a calcineurin inhibitor continues to be favored is because of demonstrated steroid-sparing effects. However, in high-risk cGVHD with thrombocytopenia, the addition of cyclosporine exerted a survival benefit over prednisone alone based on the results of sequential phase II trials in the 1980s [65,74].

Table 84.5 Standard "9 months" glucocorticoid therapy for cGVHD.

Week	Dose of prednisone (mg/kg)
1–2	1.0 daily
3	1.0 alternating with 0.5 every other day
4	1.0 alternating with 0.25 every other day
5	1.0 alternating with 0.12 every other day
6	1.0 alternating with 0.06 every other day
7–20	1.0 every other day
21	0.9 every other day
22	0.8 every other day
23	0.7 every other day
24	0.6 every other day
25–40	0.5 every other day
	After resolution of all reversible manifestations, taper prednisone by 10% every 2–4 weeks as tolerated

Secondary therapy

Systemic therapy is changed in approximately 60% of patients during the first 3 years because of inadequate response to primary therapy for cGVHD [75]. In general, secondary systemic therapy is *not* indicated while there is continuing improvement in at least one manifestation of cGVHD without progression of any other manifestations. Secondary therapy is generally indicated whenever (1) clinical manifestations progress within 1 month in a previously involved organ or a new organ becomes involved, (2) manifestations show no improvement within 2 months on the originally prescribed medications, (3) daily prednisone doses cannot be tapered below 1.0 mg/kg within 2 months, or (4) manifestations worsen during later attempts to taper prednisone below 0.5 mg/kg/day [72]. Earlier initiation of secondary therapy would be appropriate in severe cGVHD. In other scenarios, a longer trial of initial therapy would be appropriate and examples include sclerotic manifestations where slow improvement is expected, or BO where improvement in the FEV_1 occurs slowly, if at all, and stability of the FEV_1 is generally considered a success. Cryptogenic organizing pneumonia, which may occur in either acute GVHD or cGVHD, is another exception since relapses are frequent with steroid tapers that follow the alternate-day schema of Table 84.5. Inability to tolerate higher doses of prednisone because of debilitating steroid myopathy, avascular necrosis, poorly controlled diabetes, or renal dysfunction due to cyclosporine-associated thrombotic microangiopathy are common reasons that prompt earlier changes to secondary treatment. Situations that lead to delayed initiation of secondary therapy are not unusual when the next-in-line agents have a high risk of toxicity, and especially when multiple therapies have already been exhausted.

A comprehensive review of published reports between 1990 and 2011 showed numerous deficiencies in studies of secondary systemic treatments for cGVHD [76]. A total of 60 studies were selected for review after excluding 26 studies that contained fewer than 10 patients, case reports, and phase III studies. Most studies relied on the unfounded assumption that any improvements after the study therapy must have been caused by the study therapy. Major deficiencies in ~90% of the studies were the lack of a suitable comparison group that could serve as a valid historical benchmark, the absence of a formal statistical hypothesis, and the absence of a consistent treatment due to variations in patient selection. Most studies failed to measure response at a fixed time point and simply selected best response at any time as the end-point. Lack of uniformity in the evaluation and reporting of cGVHD responses was highlighted by the 2005 NIH Consensus Conference [77] and validation of standardized response criteria that correlate with patient- and physician-perceived clinical improvement or worsening are only just starting to emerge [4,10–13]. One other problem in determining the efficacy of a therapy in cGVHD is that early responses may not necessarily translate into subsequent tolerance without recurrent malignancy [78]. All of these issues notwithstanding, physicians are often faced with having to choose (multiple) secondary therapies. The report by Martin et al. indicated that the seven most frequently studied therapies in descending order were photopheresis, mycophenolate mofetil, thalidomide, sirolimus or everolimus, rituximab, and methotrexate [76]. A list of 30 secondary therapies for cGVHD has been developed that includes supporting evidence and recommendations

Table 84.6 Considerations for use of the most published agents in cGVHD as second-line therapy or beyond

Extracorporeal photopheresis (ECP)	
Mechanism of action	Direct apoptosis of leukocytes (especially lymphocytes) and reinfusion of these cells seems to generate tolerogenic responses by reported mechanisms that include interference with dendritic cell maturation, modulation of cytokine production, and expansion of regulatory T (Treg) cells
Toxicity concerns	Limited: blood loss from the extracorporeal circuit, hypocalcemia depending on anticoagulant used, mild cytopenia, catheter-associated bacteremia, but overall infection risks not increased over standard therapy
Significant interactions	None
Infection concerns	Viral or fungal infection not increased
Convenience	Inconvenient; requires travel to ECP centers for up to many months. Complex schedule typically 2 per week (week 1), 2 per week (weeks 2–12), and 2 per month thereafter. Often requires central line placement for the procedure
Expense concerns	Very expensive
Mycophenolate mofetil (MMF)	
Mechanism of action	Non-competitive inhibitor of IMPDH, the rate-limiting step for de novo purine synthesis on which lymphocytes depend
Toxicity concerns	Dose-related cytopenia and gastrointestinal toxicity; consider risk:benefit carefully when GVHD includes GI tract. Enteric-coated mycophenolic acid (Myfortic) may be better tolerated
Significant interactions	May compound cytopenia when used with other myelosuppressive drugs
Viral infection concerns	Moderately high, especially if used with high-dose steroids in already lymphopenic patients
Convenience	Smallest pill formulations are 250 mg (MMF) or 180 mg (Myfortic) and IV formulation is available
Expense concerns	Moderately expensive
Comment	Randomized phase III study in cGVHD showed no benefit of adding MMF to standard therapy (prednisone plus CNI [69]) but no definitive data on its use as secondary therapy and without a CNI
Thalidomide	
Mechanism of action	Immunomodulatory, although specific actions are not fully understood. Under some conditions suppresses TNF-α
Toxicity concerns	Neutropenia, sedation, constipation, numbness, neuropathy frequent at >200 mg/day. Must counsel women of child-bearing potential and sexually mature males how to avoid birth defects
Significant interactions	Not usually clinically significant
Viral infection concerns	No considered to be a high risk
Convenience	50-mg capsule is smallest formulation; no IV form available
Expense concerns	Moderately expensive
Comment	May be most logical to try in the treatment of myeloma patients who have cGVHD
Sirolimus (rapamycin)	
Mechanism of action	Binds to FK-binding protein complex and blocks mTOR causing cell cycle arrest in G1; T cells are the most sensitive. Other mechanisms include blocking CD28 costimulation, prevention of dendritic cell antigen presentation and maturation, impairment of B-cell activation and immunoglobulin production
Toxicity concerns	Most clinically relevant are reversible cytopenia, hypertriglyceridemia, nephrotoxicity (HUS/TMA) and neurotoxicity (TTP) when combined with CNIs. Less common clinically relevant are transaminase elevations, edema, arthralgias, delayed wound healing and non-infectious pneumonitis.
Significant interactions	Sirolimus is a substrate for CYP3A4 and P-gp and attention to concomitant therapies that interact with CYP3A4 and P-gp is necessary. Critical interaction mandates an initial 90% sirolimus dose reduction when starting voriconazole (7% reduction for posaconazole, 25% reduction for fluconazole). Sirolimus may increase risk for rhabdomyolysis during HMG-CoA reductase inhibitor therapy. In patients who develop HUS, the CNI should be stopped and sirolimus dose should be adjusted to ensure trough level <10 ng/mL. If total bilirubin >2 mg/dL, sirolimus dose should be reduced by 30%.
Viral infection concerns	Moderate
Convenience	Oral formulations only: 0.5, 1, and 2-mg tablets, and 1 mg/mL oral solution. Target levels 3–12 ng/mL (<10 ng/mL if also on a CNI). Consider $T_{½}$ 57–62 hours when adjusting dose and checking levels
Expense concerns	Moderately expensive
Rituximab	
Mechanism of action	Mature B-cell-depleting chimeric anti-CD20 monoclonal antibody that suppresses antibody-dependent and, via T-cell collaboration, antibody-independent B-cell cGVHD-associated mechanisms
Toxicity concerns	Mostly well tolerated. The extent to which rituximab exacerbates cGVHD associated B-cell lymphopenia and hypogammaglobulinemia is unclear; infectious complications have been reported.
Significant interactions	Not usually clinically significant
Viral infection concerns	Low
Convenience	IV only; usually 375 mg/m^2 given weekly for 4 doses with possibility to repeat 4 doses given weekly or monthly (one group reported similar results if given at low dose, 50 mg/m^2) [92]
Expense concerns	Very expensive
Comment	Most successes reported for deep and superficial skin and autoimmune manifestations
Pentostatin	
Mechanism of action	Nucleoside analog that potentially inhibits adenosine deaminase. Broad activities in GVHD include marked reduction of CD4 and CD8 T cells, significant B-cell depletion and lowering of IgG levels.
Toxicity concerns	Myelosuppression, renal toxicity, neurotoxicity, and reversible elevation of liver function tests. It is advisable to reduce dose to 2 mg/m^2 if ANC <0.5 × 10^9/L, platelets <20 × 10^9/L, or if creatinine clearance 30–50 mL/min/1.73 m^2 (and hold if <30 mL/min/1.73 m^2). Do not give during severe infection. Stop or withhold therapy for neurotoxicity
Significant interactions	Not usually clinically significant.
Viral infection concerns	Moderate but apparently less that in the acute GVHD setting when pentostatin is dosed differently. Consider viral plasma PCR monitoring in patients with delayed numeric immune reconstitution.
Convenience	IV formulation only: 4 mg/m^2 every 2 weeks
Expense concerns	Very expensive
Comment	The largest study was in pediatrics [93].
Low-dose methotrexate	
Mechanism of action	Immunomodulatory and anti-inflammatory properties at low doses are mediated not through inhibition of DHFR and DNA synthesis but through release of adenosine, which binds to A_2 receptors and inhibits oxidative burst in activated neutrophils and the adhesion of neutrophils to endothelial cells. Adenosine modifies cytokine production by neutrophils, monocytes, macrophages, and T cells, decreasing production of TNF-α, IFN-γ, IL-6, and IL-8, and increasing production of IL-10 and IL-4. Methotrexate is converted intracellularly from monoglutamated derivatives to long-lasting polyglutamates, which explains the efficacy of the low-dose weekly regimen

(*Continued*)

Table 84.6 (*Continued*)

Toxicity concerns	Generally low. Myelosuppression uncommon. Liver toxicity uncommon. Cheilitis. Alopecia. Avoid in renal failure or in patients with large third-space fluid accumulations
Significant interactions	Not usually clinically significant
Viral infection concerns	Low
Convenience	Easy to prescribe (7.5 mg/m^2 per week), but important patient communication needed to avoid life-threatening overdose
Expense concerns	Inexpensive
Comment	Consider in mild fasciitis or arthralgias that are considered to be a cGVHD manifestation
Imatinib	
Mechanism of action	Tyrosine kinase inhibitor, PDGFR inhibitor
Toxicity concerns	Cytopenias, edema
Significant interactions	Inhibits CYP3A4 and may increase the concentration of statins, CNIs, and sirolimus
Viral infection concerns	Low
Convenience	Easy to prescribe. Oral formulation only: 100- and 400-mg tablets
Expense concerns	Very expensive and currently not often covered by insurance for the cGVHD indication
Comment	Most successes have been in sclerotic/fibrotic types of cGVHD based on early reports [40,41]
Hydroxychloroquine	
Mechanism of action	Antimalarial agent. Interferes with antigen processing and presentation. Reduces production of IL-1, IL-6, and TNF-α, and also decreases calcium signaling in T cells. Reduces proliferation and cytotoxicity associated with allorecognition
Toxicity concerns	GI symptoms, retinal damage and corneal opacities (need annual eye exams), myositis and polyneuropathy, rare cytopenias
Significant interactions	Not usually clinically significant
Viral infection concerns	Low
Convenience	Easy to prescribe but oral formulation only
Expense concerns	Relatively inexpensive
Comment	Randomized phase III study in children showed no benefit of adding hydroxychloroquine to standard therapy (prednisone plus CNI [70]) but no definitive data on its use as secondary therapy

IMPDH, inosine monophosphate dehydrogenase; BMT CTN, Blood and Marrow Clinical Trials Network; mTOR, mammalian target of rapamycin; HUS, hemolytic uremic syndrome; TMA, thrombotic microangiopathy; TTP, thrombotic thrombocytopenic purpura; EBV, Epstein–Barr virus; CMV, cytomegalovirus; ANC, absolute neutrophil count; CNI, calcineurin inhibitor; PDGFR, platelet derived growth factor receptor; P-gp, P-glycoprotein; $T_{1/2}$, terminal half-life.

for use by the Working Groups of the 2009 German–Austrian–Swiss Consensus Conference [79]. Because comparative data demonstrating superior efficacy for any particular agent over others are not available, therapeutic choices beyond primary therapy should be guided by the effects and toxicities of prior treatments, patient comorbidities, convenience, expense, familiarity of the physician with the agent, prior experience of the physician, and sensitivity to the patient's own preference. Key practical considerations are highlighted for some of the available agents in Table 84.6. Clinical practice aspects on how we treat cGVHD have been reported [80].

Ancillary therapy and supportive care

Chronic GVHD manifestations may affect multiple organs over the several years that it takes for tolerance to develop and for discontinuation of immunosuppressive therapy to occur. Current therapies often produce partial responses and GVHD flares occur frequently with attempts to taper systemic therapy. Late effects in multiple organs may arise through the interaction of pre-transplant chemoradiotherapy, cGVHD itself, infection associated with immune deficiency, and even the toxicities of cGVHD therapy. It follows that ancillary therapy and supportive care to prevent infections, optimize nutrition, ameliorate morbidity, and optimize functional performance and capacity are integral to cGVHD management (http://www.asbmt.org/?page=GuidelineStatements). The NIH consensus recommendations define "ancillary therapy" as any intervention such as topical corticosteroids, cyclosporine eye drops or any other non-systemic therapeutic intervention directed at control of symptoms. The term "supportive care" includes a broad spectrum of interventions that are directed at control of organ-specific or systemic symptoms. Supportive care includes antibiotics for prevention of infections, management of osteoporosis, metabolic problems, physical therapy, and a number of educational, preventive, and psychosocial measures. Ancillary and supportive care therapies are commonly added to systemic immunosuppressive therapy. Occasionally, their use may circumvent the need for systemic therapy or allow doses of systemic agents to be reduced. A summary of ancillary therapy and supportive care interventions guidelines is presented in the Table 84.7. Specific dispensary information is also available from the website http://www.asbmt.org/?page=GuidelineStatements.

Infection is the most common cause of mortality in patients with cGVHD and infection prophylaxis requires special emphasis. Recommendations supported by published evidence are more often derived from studies with patients who had conditions other than cGVHD. All patients with cGVHD are considered at risk for infection with encapsulated bacteria, particularly *Streptococcus pneumoniae*, but also *Haemophilus influenzae* and *Neisseria meningitidis*. Encapsulated organism prophylaxis should be given to all patients with cGVHD while systemic immunosuppressive therapy is being given. Optimal selection of prophylaxis considers local patterns of pneumococcal resistance and individual allergies or toxicities associated with available antibiotic choices that include penicillin, cotrimoxazole, second-generation cephalosporins, quinolones, and azithromycin. None of these strategies has been tested in randomized trials but historical data show fulminant septic events in patients without prophylaxis due to the profound immunosuppression. When pneumococcal resistance patterns permit, a daily cotrimoxazole regimen can provide prophylaxis against *Pneumocystis jirovecii* pneumonia (PJP), pneumococcus, and to some extent toxoplasmosis and nocardia.

Although no studies have evaluated the degree of protection provided by vaccination against encapsulated organisms in patients with cGVHD, expert consensus opinion advocates their use beginning as early as 3–6 months after transplant [82]. since the T-cell-dependent conjugated vaccines are more effective that the older polysaccharide vaccines and the risk of adverse outcomes with vaccination is low. Nonetheless, some centers require an arbitrary numeric level of immune reconstitution if vaccinations for pneumococcus, *H. influenzae* type b and *N. meningitidis* are given before 1 year after transplantation [e.g. serum immunoglobulin G (IgG) level >400 mg/dL, CD4 T cells >200/μL and CD19 B cells >20/μL].

Table 84.7 Summary of ancillary therapy and supportive care interventions

Organ system	Preventive intervention	Treatment intervention
Skin and appendages	UVA/UVB photoprotection Surveillance for malignancy	Intact skin: topical emollients, corticosteroids, antipruritics, and others (e.g. PUVA, tacrolimus) Erosions/ulcerations: microbiologic cultures, topical antimicrobials, protective films or other dressings, debridement, hyperbaric oxygen, wound care specialists
Mouth and oral cavity	Maintain good oral/dental hygiene. Consider routine dental cleaning and endocarditis prophylaxis. Surveillance for infection and malignancy	Topical high- and ultrahigh-potency corticosteroids and analgesics. Therapy for oral dryness with salivary stimulants (sugar-free gum, cevimeline, pilocarpine)
Eyes	Photoprotection Surveillance for infection, cataracts, increased intraocular pressure	Artificial tears, ocular ointments, topical corticosteroids or cyclosporine, punctal occlusion, humidified environment, occlusive eye wear, moisture chamber eye glasses, cevemiline, pilocarpine, tarsorrhaphy, gas-permeable scleral lens or bandage contact lens, autologous serum tears, microbiologic cultures, topical antimicrobials, doxcycline for blepharitis
Vulva and vagina	Surveillance for estrogen deficiency, infection (herpes simplex virus, human papilloma virus, yeast, bacteria), and malignancy	Water-based lubricants, topical high- and ultrahigh-potency corticosteroids or calcineurin inhibitors, dilators, surgery for extensive synechiae/obliteration, early gynecology consultation
GI tract and liver	Surveillance for infection (viral, fungal)	Rule out other potential etiologies. Dietary modifications, enzyme supplementation for exocrine pancreatic malabsorption, gastroesophageal reflux management, esophageal dilatation, ursodeoxycholic acid
Lungs	Surveillance for infection (*Pneumocystis jirovecii*, viral, fungal, bacterial)	Rule out other potential etiologies (e.g. infection, gastroesophageal reflux). Inhaled corticosteroids, bronchodilators, supplementary oxygen, pulmonary rehabilitation Consideration of lung transplantation
Hematopoietic	Surveillance for infection (cytomegalovirus, parvovirus)	Rule out other potential etiologies (e.g. drug toxicity, infection) Filgrastim, immunoglobulin for immune cytopenias
Neurologic	Calcineurin inhibitor drug level monitoring Seizure prophylaxis including blood pressure control, electrolyte replacement, anticonvulsants	Occupational and physical therapy, treatment of neuropathic syndromes with tricyclic antidepressants, selective serotonin reuptake inhibitors or anticonvulsants
Infectious disease	Prophylaxis against *Pneumocystis jirovecii*, encapsulated bacteria, shingles Consider prophylaxis against molds during treatment of cGVHD with prednisone and a history of proven or probable mold infection	Organ-specific antimicrobial agents Empiric parenteral broad-spectrum antibacterial coverage for fever
Immune reconstitution	Consider immunizations only with killed vaccines (influenza, conjugates against *H. influenzae* type B, tetanus/diphtheria/pertussis, pneumococcus and meningococcus, hepatitis A and B, polio) Immunoglobulin replacement based on levels through day 365 post-transplant	Consider immunoglobulin replacement based on levels for recurrent sinopulmonary infections
Musculoskeletal	Surveillance for decreased range of motion, bone densitometry, calcium levels and 25-OH-vitamin D. Consider MR imaging to detect avascular necrosis in patients with large joint pain Physical therapy, calcium, vitamin D, and consider bisphosphonates (or hormone replacement therapy if appropriate) if on prednisone	Physical therapy Consider bisphosphonate therapy for osteopenia, osteoporosis and early avascular necrosis Consider referral to orthopedic surgeon for avascular necrosis (immobilization brace, limited weight bearing with crutches, core decompression, osteochondral allografting, joint resurfacing, total joint arthroplasty)
Endocrine	Surveillance for fasting hyperglycemia, hyperlipidemia, and, if clinically indicated, consider cortisol stimulation testing to rule out secondary adrenal insufficiency	Diabetes management Lifestyle intervention and lipid-lowering agents Adrenal replacement hydrocortisone dosing

MR, magnetic resonance; PUVA, psoralen and ultraviolet irradiation.

Vaccination with TIV (trivalent influenza vaccine) but never the LAIV (live attenuated influenza vaccine) is advised for all recipients who are at least 6 months out from HCT and, in the midst of an influenza epidemic, as early as 4 months after HCT. Some experts advocate empirical treatment of influenza with neuraminidase inhibitors during influenza outbreaks, using prediction rules based on symptoms and signs, although there is no evidence to support this practice [81]. Any live virus, including the live attenuated MMR (measles/mumps/rubella), varicella, and zoster vaccines, should not be given. Household contacts should not be given oral polio vaccine. Additional details about post-transplant vaccination are covered in Chapter 106. Universal administration of IVIG after HCT has not been shown to confer clinical benefit and should be avoided. Intravenous immunoglobulin supplementation may be considered for patients >90 days after HCT who have recurrent sinopulmonary infections and serum IgG levels <400 mg/dL.

Invasive mold infections are a significant risk for patients with severe cell-mediated immunodeficiency caused by cGVHD and its treatment. Although controversies remain about appropriate therapy duration, dosing and levels, drug interactions, and resistant breakthrough infections, many centers prescribe primary prophylaxis with posaconazole or voriconazole for patients considered at high risk for invasive mold infections such as those with cGVHD and on higher doses of steroids (>0.5–1.0 mg/kg/day) [82,83]. Most centers also prescribe secondary prophylaxis during systemic therapy for cGVHD; selection of an appropriate prophylactic drug is based on the specific pathogen that caused the previous invasive mold infection and the response to antifungal therapy during that episode. See also Chapter 86.

All patients who are receiving systemic therapy for cGVHD should receive and continue prophylaxis against PJP until 6 months after stopping immunosuppressive therapy according to consensus guidelines [82]. First-choice PJP prophylaxis is cotrimoxazole with alternatives being dapsone, atovaquone, and aerosolized pentamidine.

Some experts use long-term antiviral prophylaxis to prevent recurrent herpes simplex and varicella zoster virus infection among HCT recipients with severe, long-term immunodeficiency. If a patient with cGVHD is exposed to varicella (either primary or post-vaccination illness), VZV IG, if available, should be given within 96 hours, or valacyclovir may be given until 22 days from exposure. Patients who begin cGVHD therapy who have lymphopenia and/or a history of cytomegalovirus (CMV) reactivation during the first 3 months are at higher risk of late CMV reactivation and death [84]. Some centers continue to monitor CMV viremia after day 100 by weekly to every other week polymerase chain reaction (PCR) testing based on individual risks, followed by preemptive therapy. See also Chapter 87.

Monitoring

Because cGVHD therapy spans 1–3 years or longer, and its manifestations are by nature protean, close serial monitoring of all organ systems is recommended to promote early detection and intervention [81]. This first involves a directed interval medical history and physical examination and review of medications. It is worth remembering that the reported cumulative incidence of sclerotic manifestations is 20% at 3 years [85] and joint involvement, as defined by NIH joint/fascia score ≥1, is present in about 30% of patients with cGVHD, often affecting the wrists or ankles [86]. Comprehensive cGVHD assessments with documentation of NIH scores are advised every 3 months if disease tempo is aggressive or uncertain and every 6 months if more stable to allow subtle manifestations to be detected, monitored carefully, and/or treated early with the hoped for goal of avoiding progression to highly morbid, difficult to treat, and, fairly often, irreversible forms of cGVHD. This can be accomplished effectively in clinical practice by following a streamlined and reliable method [87]. Standardized medical photographs can be invaluable if taken at a predefined (days 80–100) baseline, at initial cGVHD diagnosis, and every 6 months if skin and/or joints are involved until resolution of reversible manifestations or discontinuation of therapy. Digital images can be stored electronically and made accessible for serial comparisons of the current state of a patient's skin lesions and/or limited joint mobility. Combined use of the NIH joint score and the photographic range of motion scale (P-ROM, Figure 84.22) are recommended tools to assess joint GVHD; the NIH score better reflects joint improvement and the P-ROM scale better reflects joint worsening from baseline (Y. Inamoto and P.A. Carpenter, unpublished data).

Routine blood monitoring includes the cord blood cell and differential, chemistry panel, therapeutic drug levels, IgG level, lipid profile, 25-OH-vitamin D, thyroid function, and ovarian and testicular function. Annual bone mineral density testing is appropriate for patients receiving glucocorticoids or abnormal prior tests. Pulmonary function test monitoring is advised to determine the NIH lung score, or to follow the LFS (composite score of FEV_1/DLCO) for those with known BO. Spirometry with lung volumes and corrected diffusing capacity is usually performed every 3–6 months, based on cGVHD disease tempo, to monitor for airflow obstruction. If airflow obstruction is new and moderate or severe and of uncertain tempo, or progressing rapidly, then limited spirometry is followed as often as monthly until the FEV_1 stabilizes.

Consultation with subspecialists in dental/oral medicine, gynecology, ophthalmology, rehabilitation medicine, pain, and supportive care might also be indicated. The scope and frequency of monitoring should be individualized as clinically indicated and ranges from monthly to at least yearly. More frequent monitoring is advised for those with active cGVHD and especially during the high-risk periods such as during tapering of medications. Especially challenging cases might benefit from referral for consultation at a major national center that has multidisciplinary expertise in cGVHD.

Graft-versus-leukemia effect

A landmark registry study by Horowitz et al. investigated GVL effects among 2254 patients with acute leukemia in first remission or chronic myeloid leukemia in first chronic phase, most of whom received HLA-identical sibling bone marrow after high-dose conditioning [88]. Patients who had only cGVHD or both acute GVHD and cGVHD had lower relative risk (RR) of relapse than patients without GVHD (RR 0.43, $p = 0.01$ and RR 0.33, $p = 0.0001$, respectively). In the same analysis, relapse rates in patients who received identical twin grafts or T-cell-depleted grafts were at increased risk of disease relapse (RR 2.09, $p = 0.005$ and RR 1.76, $p = 0.002$, respectively).

Using similar methodology in a large study cohort to examine GVT effects in patients after high-dose conditioning and allogeneic HCT for advanced non-Hodgkin lymphoma, Bierman et al. found no evidence that relapse risk was affected by acute GVHD or cGVHD, T-cell depletion, or identical twin grafts, suggesting that clinical expression of GVL/T effects may depend on the underlying disease and/or the number or nature of prior therapies [89]. Lee et al. analyzed the effects of cGVHD severity among 3472 patients who received high-dose conditioning and allogeneic HCT from related or unrelated donors for acute or chronic myeloid leukemia [25]. This large study showed that patients with mild, moderate, or severe cGVHD had lower relapse rates than patients without cGVHD, but there was no evidence that increasing cGVHD severity was linked to decreasing relapse rates. Equally important, NRM was not increased by the presence of mild cGVHD but was increased by severe cGVHD. Hence patients with mild cGVHD had the best disease-free survival, those without cGVHD had disease-free survival that was similar to that in patients with moderate cGVHD, and patients with severe cGVHD had the worst disease-free survival. These findings have practical implications and support pursuing effective treatments of moderate and severe cGVHD after myeloablative conditioning.

There are surprisingly few data on GVT effects after RIC and HCT, a setting where curative effects of HCT are almost entirely immunologically dependent. Baron et al. analyzed GVT effects in 322 patients given HLA-matched related or unrelated donor grafts after RIC transplantation and noted a higher probability of achieving complete remission in patients who developed extensive cGVHD (HR 1.7, $p = 0.07$) [90]. Grade II–IV acute GVHD had no significant impact on the risk of disease relapse/progression. Acute GVHD was associated with an increased risk of NRM and decreased probability of progression-free survival. In contrast, extensive cGVHD was associated with reduced risk of disease relapse/progression (HR 0.4, $p = 0.006$) and increased probability of progression-free survival ($p = 0.003$). These findings suggest that cGVHD may contribute substantially to the success of RIC transplants for malignant disease.

Recently, Inamoto et al. explored the influence of NIH-defined cGVHD and immunosuppressive therapy (IST) on risk for recurrent malignancy after high-dose conditioning and allogeneic HCT [91].

Rates and hazard ratios of relapse and mortality were analyzed according to GVHD and IST as time-varying covariates. Adjusted Cox analyses showed that acute GVHD and cGVHD were both associated with statistically similar reductions in risk of relapse beyond 18 months after HCT but not during the first 18 months. In patients with GVHD, resolution of GVHD followed by withdrawal of IST was not associated with a subsequent increase in risk of relapse. In patients without GVHD, withdrawal of IST was associated with a reduced risk of relapse during the first 18 months, but the risk of subsequent relapse remained higher than in patients with GVHD. Therefore, the association of GVHD with risk of relapse changes over time after HCT. In patients without GVHD, early withdrawal of IST might help to prevent relapse during the first 18 months, but other interventions would be needed to prevent relapse at later time points.

Future directions

Since the previous edition of this book, there has been considerable progress in the prospective validation of many of the new NIH chronic GVHD assessment tools. With the establishment of the North American Chronic GVHD Consortium and BMT CTN, the field is now much better organized and well poised to conduct multicenter observational and therapy intervention trials effectively. The emerging understanding of cGVHD biology is still rudimentary and lags significantly behind the recent developments in acute GVHD. Strategies for acquisition of tissue, blood, saliva, and other human samples should be aggressively implemented in transplantation and cGVHD therapy studies to help improve our understanding of cGVHD biology, develop better diagnostic and treatment strategies, and find more effective and less toxic drugs that do not interfere with GVT effects. The development of validated and practical cGVHD response criteria and a cGVHD activity score are paramount and urgent unmet needs. The straightforward 0–3 NIH individual organ severity scoring, while initially intended as a baseline assessment tool, holds promise as a standalone response assessment tool that correlates well with patient and physician perceived improvement and worsening in a number of organs [4,10,12].

It is hoped that greater diligence regarding good study design principles and the use of improved and validated response assessment tools will be able to help identify better promising candidate treatments in robust multicenter phase II studies that could be taken forward in phase III studies of secondary or primary therapy. The results of these improved communal efforts are expected to lead to better survival and elimination of disabling cGVHD in the future.

Acknowledgments

The authors would like to thank Drs. Edward Cowen and Maria Turner of the National Cancer Institute Dermatology Branch, Janine Smith of the National Eye Institute and Mark Schubert of the Fred Hutchinson Cancer Research Center, who kindly allowed us to use photographs from their archives. Our gratitude also goes to Dr Sandra Mitchell for her expert assistance with selecting and composing the photographs for this chapter.

CHAPTER 85

Bacterial Infections

Helen L. Leather and John R. Wingard
University of Florida College of Medicine, Gainesville, FL, USA

Introduction

Susceptibility to infection has posed one of the most formidable challenges in the clinical management of patients undergoing hematopoietic cell transplantation (HCT) from the earliest days of this treatment. A variety of advances in infection control have permitted major strides in the supportive care of transplant recipients, and these have translated into improved outcomes. Increased understanding of the pathogenesis of infectious syndromes, introduction of new antimicrobial agents, adoption of empirical antibiotics during aplasia before engraftment, development of novel strategies to prevent and treat infections, and recognition of the contributory role of infectious pathogens to the morbidity of other transplant complications, especially graft-versus-host disease (GVHD), have all been responsible for improved survival rates. Advances including peripheral blood hematopoietic cells as alternative sources of bone marrow cells have resulted in faster engraftment of both platelets and neutrophils, leading to shorter lengths of stay, fewer days of fever, and less antibiotic use. The increasing use of reduced-intensity transplants, which are associated with less gastrointestinal and overall chemotherapy-induced toxicity, are also associated with reduced infectious complications. However, shifts in the patterns of opportunistic pathogens, changing antimicrobial susceptibility, differences in host immunodeficiency with implementation of new immunosuppressive regimens for GVHD, introduction of new conditioning regimens for use in the treatment of solid tumors, and the increasing use of alternative donors continue to pose new and different challenges and opportunities for the management of infectious complications.

Biology of bacterial pathogens

Bacteria are found in a great variety of environments. They are classified as prokaryotic microorganisms distinguished by absence of a membrane enclosing their DNA and absence of other membrane-bound organelles. More than 2500 species of bacteria are known. Classification consists of the broad grouping of medically significant bacteria based on their staining properties using the Gram stain (positive or negative), morphology (cocci and bacilli), and oxygen tolerance (aerobic or anaerobic). Other properties, including DNA and RNA homology, ribosomal RNA homology, biochemical properties, specialized growth requirements, and antigenic attributes, have also been used for further characterization.

In general, bacteria have cell walls made of peptidoglycan, a molecule unique to bacteria and thus a target for many antimicrobial agents. The cell wall provides the basic shape of the organism and confers rigidity. The Gram stain detects differences in the cell wall structure of bacteria. These differences are useful in distinguishing both antibiotic susceptibility and the potential for interacting with host defenses. Gram-positive bacteria have walls that consist of thick layers of peptidoglycan, teichoic acids, teichuronic acids, and other polysaccharides. Inhibition of peptidoglycan synthesis is the mechanism of action of a variety of antibiotics, including penicillins, cephalosporins, and glycopeptides. The cell wall of Gram-negative organisms consists of an outer membrane composed of protein, lipopolysaccharide (LPS), and phospholipid, and a thin inner layer of peptidoglycan. Protein components of the membrane, known as porins, serve as permeability conduits for hydrophilic molecules. The size and number of porins determine permeability to various molecules, including antibiotics.

Several properties are important in the ability of a given bacterial species to colonize or invade the human host (Table 85.1). These include adherence to host cells, the capacity to acquire iron from the host, elaboration of toxins, and successful competition with other microbial colonizers for nutrients. Adhesins on the surface of bacteria interact with specific receptors on host tissue targets. Differences in either the adhesin molecules or host cell receptor binding determine tissue tropism. Various structures exist on the surface of medically important bacterial pathogens, which are important virulence factors. A capsule of polysaccharide can afford protection against phagocytosis. Immunologic diversity of such capsules within species is common (the basis for serotyping), and can permit evasion of the normal host defenses since opsonizing antibodies directed against the specific antigens of the capsule are important for phagocytosis. In Gram-negative bacteria, pili are important means by which bacteria adhere to epithelial cells. Gram-positive bacteria may have surface proteins (e.g. the M protein of group A streptococci or staphylococcal protein A) that serve as virulence factors.

Bacterial products such as superantigens may provoke host responses that are deleterious to the maintenance of host physiology. Exotoxins produced during exponential growth and released by both Gram-positive and -negative bacteria interfere with normal host cell metabolism and contribute to host toxicity. Certain toxins, known as bacteriocins, are elaborated to enhance an organism's competition with other microorganisms within the normal flora to establish an ecologic niche. The production of certain extracellular enzymes, such as hyaluronidase, neuraminidase, elastase, and collagenase, facilitates overcoming anatomic barriers and promotes spread past tissue barriers. Proteins may be produced that facilitate

Table 85.1 Bacterial virulence factors

Molecule	Effects on host
Exotoxins	Interfere with cellular physiology
Endotoxins	Elicit sepsis syndrome
Bacteriocins	Establish ecologic niche in host flora
Exoenzymes	Disrupt anatomic barriers, facilitate tissue invasion
Proteases	Degrade humoral immune responses and complement
Polysaccharide capsules	Resist humoral immunity and phagocytosis
Plasmids, phages, transposons	Confer antibiotic resistance, multiple virulence properties, rapid adaptation to environment
Regulatory factors	Allow rapid adaptation to environmental changes
Biofilms	Form barrier to exclude antibiotics

Table 85.2 Targets for various antibiotics

Bacterial target	Antibiotics
Peptidoglycan synthesis	Penicillins, cephalosporins, glycopeptides
Lipopolysaccharide	Antibodies to endotoxins or cytokines mediating sepsis syndrome
Penicillin-binding proteins	Penicillins, cephalosporins, carbapenems
β-Lactamases	Clavulanic acid, sulbactam, tazobactam
Ribosomes	Aminoglycosides, macrolides, tetracyclines, chloramphenicol, oxazolidinones, streptogramins
RNA polymerases	Rifamycins
Folic acid synthesis	Sulfonamides, trimethoprim
DNA gyrase	Fluoroquinolones
Bacterial membrane	Daptomycin
Depolarization	Oxazolidinones, linezolid; streptogramins, quinupristin/dalfopristin

entry into host cells. Disruption of host humoral responses by proteases permits traversing of mucosal barriers and survival in extracellular tissue and serum.

Avoidance of phagocytosis or killing of microorganisms once ingested is the role of a variety of virulence factors. The polysaccharide capsule of many organisms is designed both to resist humoral immunity and to impede phagocytosis. Bacterial LPS (endotoxin) serves as an important barrier against bile salts, lytic enzymes, DNA, and heavy metals. LPS also contains a carbohydrate moiety (the O antigen) that resists complement binding and differs antigenically from strain to strain. The generation of such antigenic diversity is a mechanism that bacteria use to evade host humoral immune responses. LPS induces the sepsis syndrome by causing the release of a variety of proinflammatory cytokines, such as tumor necrosis factor-α, interleukin 1, interferon-γ, and various colony-stimulating factors by monocytes and macrophages, and by triggering a variety of host enzymatic mechanisms, including complement, clotting, fibrinolytic, and kinin pathways.

A number of gene products on extrachromosomal elements, such as plasmids, phages, insertion elements, and transposons, provide bacteria with mechanisms to adapt rapidly to a competitive environment, conferring antibiotic resistance and multiple virulence properties, which can be shared between a wide variety of unrelated microbes. A variety of regulatory proteins provide bacteria with the capacity to respond favorably to rapid shifts in the environment, such as temperature, iron, and pH. These proteins facilitate adherence and invasiveness and modify the expression of other proteins on the cell surface to optimize the organism's competitive stance. Antigenic variation of these proteins is the mechanism used by bacteria to evade host immune responses. These characteristics of bacteria offer a range of bacterial targets for antimicrobial agents (Table 85.2).

The host microbial flora itself may act as a barrier against opportunistic pathogens. Ordinarily, complex bacterial communities reside on the body's surfaces and within the gastrointestinal tract without deleterious effects. However, when the interactions are altered by the use of antimicrobial agents or other infection control measures, this natural barrier may be compromised, and overgrowth of pathogens that might otherwise not be capable of establishing a niche can occur. The normal commensal flora prevent the establishment of opportunistic pathogens by competition for the same nutrients or receptors on host cells through the production of toxic products, fatty acids, or other metabolites that inhibit growth of potential competitors and stimulation of the host immune system.

Some bacteria routinely cause disease in susceptible hosts who have normal defenses, and these certainly can cause morbidity in the HCT recipient. However, more commonly, infectious morbidity in the HCT recipient is caused by bacterial organisms (such as many Gram-negative bacteria, α-streptococci, and *Staphylococcus epidermidis*) that ordinarily are not pathogens. Such organisms, known as opportunistic pathogens, exploit deficits in host defenses that occur as a result of the transplant procedure or nosocomial procedures, or they exploit microbial shifts caused by infection control measures. Whether or not an opportunistic pathogen causes disease is a reflection of an interplay between its own inherent virulence, whether it has access to the host in sufficient numbers, and the state of the host defenses. Thus, effective infection control measures must address issues related to minimizing exposure to potential pathogens, the strategic use of antimicrobial agents to suppress microbial burden, and, where possible, bolstering host defenses.

Antibiotic resistance

A number of pathogens are problematic by virtue of documented resistance, including *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, vancomycin-resistant *Enterococcus faecium*, vancomycin-resistant *Staphylococcus aureus*, and methicillin-resistant *S. aureus* (MRSA). The mechanisms through which drug resistance is most commonly conferred are described below.

One of the most successful attributes that bacteria have to enhance survival is the capacity for genetic variability. This capacity is frequently used by bacterial organisms to foil clinicians' attempts to control infection by antibiotics. Through point mutations, rearrangement of entire sequences of DNA to different locations within the bacterial genome (e.g. transposons), or the transfer of DNA from one bacterial organism to another (e.g. via plasmids), development of antibiotic resistance can occur in a variety of ways (Table 85.3).

A common mechanism is inactivation of antibiotics by enzymes. For example, staphylococci and many Gram-negative bacteria produce a class of enzymes known as β-lactamases that render inactive β-lactam antibiotics, the group of molecules that includes the penicillins, the cephalosporins (e.g. cephalothin, cefuroxime, ceftazidime, cefepime, and cefoxitin), carbapenems (e.g. imipenem and meropenem), and monobactams (e.g. aztreonam). β-Lactamase genes found on transposons or plasmids permit the spread of high-level resistance widely to other classes of drugs such as the fluoroquinolones and trimethoprim–sulfamethoxazole (TMP–SMX). Unfortunately, prevalent use of the β-lactam class of antibiotics, particularly third-generation cephalosporins, has resulted in selection

Table 85.3 Mechanisms of antibiotic resistance

Mechanism	Examples	Genetic basis	Types of bacteria	Antibiotics affected
Inhibition of antibiotic by enzymes	β-Lactamases	Chromosomal, plasmids, transporons	Staphylococci, many Gram-negative bacteria	Penicillins, cephalosporins
	Acetyltransferases	Plasmids	Many Gram-negative bacteria	Aminoglycosides, chloramphenicol
	Phosphotransferases	Plasmids	Many Gram-negative bacteria	Chloramphenicol, aminoglycosides
	Nucleotidyltransferases	Plasmids	Many Gram-negative bacteria	Aminoglycosides
Reduced membrane permeability	Mutations involving porins	Chromosomal	Many Gram-negative bacteria	β-Lactams, aminoglycosides, carbapenems, nalidixic acid, fluoroquinolones
Increased efflux of antibiotics	New proteins	Chromosomal, plasmids, transporons	Many Gram-negative bacteria and staphylococci	Tetracyclines, macrolides, fluoroquinolones
Altered targets	Changes in ribosomal binding sites	Chromosomal, plasmids	Gram-positive and Gram-negative bacteria	Tetracyclines, macrolides, aminoglycosides, lincosamides
	Changes in cell wall	Chromosomal, plasmids	Gram-positive bacteria	Vancomycin, other glycopeptides
	Changes in penicillin-binding proteins	Chromosomal, plasmids	Gram-positive and some Gram-negative bacteria	Penicillins, cephalosporins
	Changes in dihydropteroate synthetase	Plasmids	Many Gram-negative	Sulfonamides
	Changes in dihydrofolate reductase	Chromosomal, plasmids	Gram-negative bacteria	Trimethoprim
	Changes in DNA gyrases	Chromosomal, plasmids	Gram-negative bacteria	Nalidixic acid, fluoroquinolones
Exclusion barrier	Biofilm formation	Chromosomal	*Staphylococcus epidermidis*, *Pseudomonas aeruginosa*	Multiple

pressure to give advantage to resistant organisms and further encourage spread. Extended-spectrum β-lactamase (ESBL)-producing organisms are an increasing cause of treatment failure. The ESBL-producing organisms are most often noted in *Klebsiella pneumoniae* and *Escherichia coli* species. Immunocompromised patients infected with these organisms should be placed on Gram-negative isolation precautions and treated with carbapenems. Carbapenem-resistant pathogens have been reported, including the *K. pneumoniae* carbapenemase (KPC) OXA carbapenemase, which is most commonly reported in *A. baumannii* isolates, and metallo-β-lactamases that are found in *Stenotrophomonas maltophilia*, *Acinetobacter* spp., *P. aeruginosa*, and *Flavobacterium* species. Carbapenem-resistant pathogens have been most commonly reported in Europe and the eastern part of the United States [1].

Reduced entry of the antibiotic into bacterial organisms by alteration of permeability, thereby restricting drug access to target sites, can be caused by mutations involving different porins. Such changes are potential mechanisms for resistance to nalidixic acid, fluoroquinolones (such as norfloxacin, ciprofloxacin, levofloxacin, and ofloxacin), aminoglycosides, and β-lactams, among others. Alternatively, resistance to some antibiotics may occur by an increase in efflux of antibiotics from the bacterial organism. This can take place by mutations in chromosomal genes or the acquisition of new genes from plasmids that lead to new membrane proteins, which reduce the retention of certain antibiotics, such as tetracyclines in Gram-negative bacteria and macrolides (such as erythromycin, azithromycin, and clarithromycin) in Gram-positive bacteria.

Alteration of the target of the antibiotic is another strategy. Multiple examples are notable. Changes in ribosomal binding sites may lead to resistance to tetracyclines, aminoglycosides, or macrolides, while changes in the amino acid residues on the constituents of cell-wall building blocks may confer resistance to antibiotics such as vancomycin. Mutations in the genes that encode for penicillin-binding proteins alter susceptibility to β-lactams, such as the penicillins and cephalosporins. A variety of target enzymes (as shown in Table 85.3) that can be changed by mutations can potentially lead to resistance to sulfonamides, trimethoprim, nalidixic acid, and fluoroquinolones, among other antibiotics.

The emergence of widespread antibiotic resistance can impede the best efforts of clinicians to control infections by various bacterial pathogens. Clearly, a cornerstone of any infection control program is the wise use of antibiotics. Repeated pleas by the Centers for Disease Control and Prevention (CDC) and other authoritative bodies for clinicians to practice antimicrobial stewardship have regrettably failed to slow the continuing emergence of drug resistance. However, several strategies have been offered [2–4]. Patients colonized or infected with resistant organisms should be isolated [3,4]. Each institution should maintain a program of surveillance for resistance to detect shifts in susceptibility and trends of problem organisms. Selected antimicrobial agents may need to be restricted to reduce the prevalence of specific resistant organisms. Certain antibiotics initiated empirically for suspected organisms (e.g. vancomycin) should be discontinued once it has been determined that they are not needed. Implementation of an antibiotic cycling program, where a particular class of antibacterial is withdrawn from use for a defined period of time as a strategy to limit bacterial resistance, has also been evaluated. Results with this approach are inconsistent. Other initiatives include limiting susceptibility reporting such that the more powerful antibacterials are not listed, and as such are less likely to be selected for treatment. Such efforts will reduce selection pressures and spread of antibiotic resistance among microbial populations [5].

Compromised host defenses

Host defenses are compromised by a variety of factors following HCT. The degree and type of compromise of host defenses change over time [6]. Three periods have been described: (1) early recovery, corresponding to the first several weeks after transplantation, the pre-engraftment phase; (2) mid-recovery, corresponding to the second and third months after transplant, the early post-engraftment phase; and (3) late recovery, corresponding to the interval beyond 3 months. Table 85.4 lists the predominant deficits that are present at various intervals.

Early recovery (phase I)

The cytoreductive agents used in conventional high-dose conditioning regimens damage rapidly dividing cell populations, particularly bone marrow progenitors and mucosal epithelial cells. For several weeks after HCT, pancytopenia and damage to the mucosal barriers are predominant deficits in the host defenses against infectious pathogens.

Table 85.4 Host defenses compromised by hematopoietic cell transplantation (HCT) that make patients vulnerable to bacterial infections

Early recovery
Neutropenia
Oral and gastrointestinal mucosal damage due to cytoreductive therapy
Skin barrier compromised by CVCs
Mid-recovery
Skin and gastrointestinal mucosal damage due to GVHD
Decreased cellular immunity due to GVHD and immunosuppressive therapy
Skin barrier compromised by CVCs
Decreased cellular immunity due to viral infections, especially CMV
Late recovery
Decreased cellular immunity; persistent with chronic GVHD
Nonspecific suppressor cells with chronic GVHD
Reduced opsonization
Decreased reticuloendothelial function
IgG subclass deficiencies

CMV, cytomegalovirus; CVCs, central venous catheters; GVHD, graft-versus-host disease; IgG, immunoglobulin G.

The duration of neutropenia varies according to the number of stem cells used to effect reconstitution, the stem-cell source, the occurrence of certain viral infections, especially cytomegalovirus (CMV), the use of certain immunosuppressive agents after transplantation as part of the GVHD prophylaxis that are also myelosuppressive, the use of agents to purge the marrow stem cells ex vivo from contaminating tumor cells, and the use of cytokines to stimulate recovery. In the autologous transplant setting, the number of prior treatment regimens, the prior use of radiotherapy, and the use of certain chemotherapeutic agents that are known to damage hematopoietic progenitors, such as nitrosoureas, melphalan, lenalidomide, and fludarabine, negatively influence the ability to obtain stem cells, leading to delays in engraftment. In the allogeneic transplant setting, human leukocyte antigen (HLA) disparity between donor and recipient, T-lymphocyte depletion of the graft, the use of umbilical cord as a stem-cell source, and inadequate conditioning of the recipient to eliminate host immune cells can also impede robust engraftment.

The duration and the depth of neutropenia independently influence the risk for infection [7]. Although the risk for bacterial infection increases incrementally as the circulating absolute neutrophil count (ANC) falls below $1000/\text{mm}^3$, the risk becomes substantial below $500/\text{mm}^3$. Bacteremia and life-threatening bacterial infection occur mostly at neutrophil counts below $100/\text{mm}^3$. Indeed, in HCT recipients, 90% of the bacterial infections occur at neutrophil counts below $100/\text{mm}^3$.

The degree of mucosal damage varies according to the preparative regimen. Busulfan, etoposide, melphalan, cytarabine, cyclophosphamide, and total body irradiation (TBI) are associated with varying degrees of mucositis. Although stomatitis is readily observable, damage to the mucosa of the entire gastrointestinal tract occurs. Attempts to quantify reliably the degree of mucosal damage are primitive, and have hampered efforts to correlate the degree of mucosal damage with infection risk along the same lines that the neutrophil count and the risk for infection have been quantified. However, the use of the D-xylose absorption test, a measure of mucosal functional integrity, has been evaluated in leukemic patients. An association between the degree of D-xylose absorption and the risk for infection has been noted [8].

Reactivation of herpes simplex virus (HSV) type 1 (which occurs in approximately 70% of seropositive patients, usually during the first or second week after HCT unless acyclovir prophylaxis is given) can lead to diffuse or localized ulceration of the mucosa of the oral cavity and the lower esophagus. This change has been associated with bacteremia from organisms that reside on the buccal mucosa. Reactivation of HSV type 2 occurs in seropositive patients and can result in urethral, labial, perineal, and perianal skin and mucosal breakdown. The use of cytotoxic agents after HCT, such as methotrexate or cyclophosphamide to prevent GVHD, can also result in exacerbation of mucositis and delays in healing, as can the corticosteroids.

The nearly universal use of indwelling central venous catheters (CVCs) today poses a risk for infection, both early and late after HCT. Such catheters compromise the integrity of the integument as a physical barrier to potential pathogens residing on the skin. Marrow puncture sites and peripheral venous catheters can also compromise the skin barrier.

The use of reduced-intensity conditioning (RIC) HCT is increasing, utilizing the immune system rather than chemotherapy to achieve disease control. The RIC regimens that are used limit the development of neutropenia, and mucositis is also significantly diminished. As a consequence, this new type of HCT has demonstrated differences in infection patterns compared with high-dose allogeneic HCT [9–12]. The incidence of early bacteremias (days 0–30) is low, and these account for a low rate of bacteremia during the first 100 days.

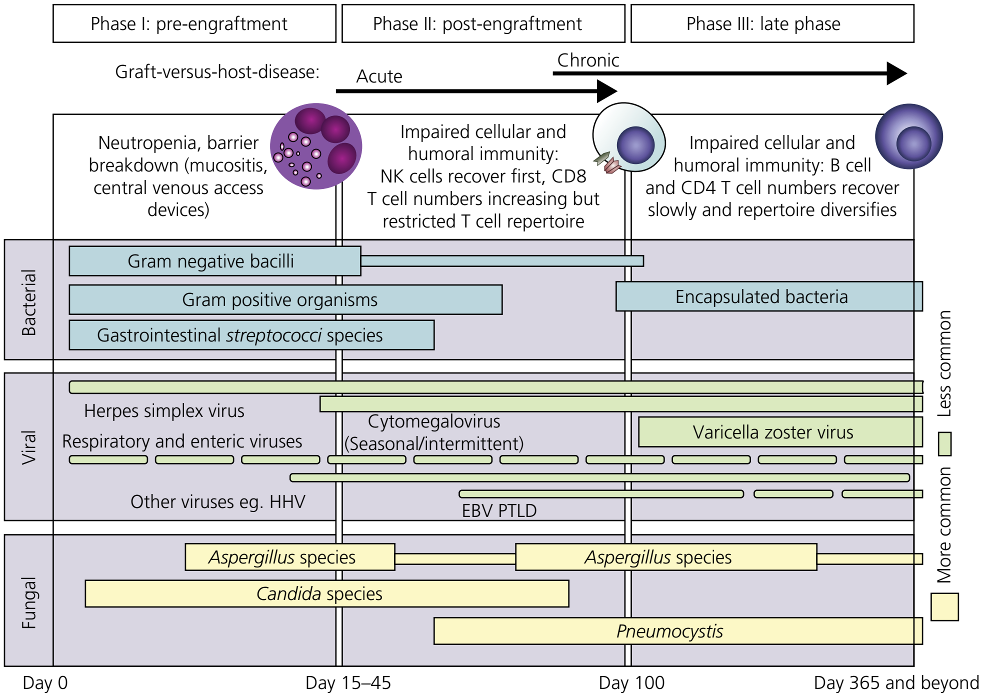
Mid-recovery (phase II)

Following engraftment, patients enter a period of profound deficiency of cellular and humoral immunity. The degree and duration of immunodeficiency are influenced by the type of HCT, the degree of donor and recipient histocompatibility, whether T-lymphocytes have been eliminated from the allogeneic marrow graft, the use of immunologic or pharmacologic purging of autologous marrow, the post-transplant immunosuppressive treatment given as GVHD prophylaxis, the occurrence of certain viral infections (especially CMV), and the occurrence and severity of GVHD. The integrity of mucosal barriers may continue to be compromised by recurrent HSV infections, the use of cytotoxic agents, and intestinal involvement by GVHD. Indwelling venous catheters typically remain in place during this period, adding to the patient's vulnerability to infection from skin bacterial flora.

Late recovery (phase III)

With time, there is gradual recovery of both cellular and humoral immunity (see Chapter 15). Generally, immune recovery is more rapid after autologous than allogeneic HCT. Among autograft recipients, those given high-dose preparative regimens (as typically used for acute leukemia) are more immunodeficient, and for longer intervals, than those given less intensive, RIC regimens, such as those used for solid tumor therapy. Immune recovery following peripheral blood autotransplantation is more rapid than after autologous marrow transplantation. Recipients of CD34-selected grafts have a slower pace of T-cell immune reconstitution [13]. Immune recovery after matched-related HLA-identical transplantation appears to be more rapid than after HLA-disparate or HLA-matched unrelated donor transplantation.

The occurrence of GVHD also influences the tempo of immune recovery and is associated with dysregulated immune responses (see Chapter 83). If chronic GVHD (cGVHD) occurs, cellular and humoral immunodeficiency may persist for months and even years [14]. Reticuloendothelial function can also be severely impaired, especially in patients with cGVHD. Immunoglobulin deficiencies can occur. Even in the face of normal levels of the isotypes, immunoglobulin G (IgG) subclass deficiencies,



Phase I: pre-engraftment
Phase II: post-engraftment
Phase III: late phase
Graft-versus-host-disease:
Acute
Chronic
Neutropenia, barrier breakdown (mucositis, central venous access devices)
Impaired cellular and humoral immunity: NK cells recover first, CD8 T cell numbers increasing but restricted T cell repertoire
Impaired cellular and humoral immunity: B cell and CD4 T cell numbers recover slowly and repertoire diversifies
Bacterial
Gram negative bacilli
Gram positive organisms
Gastrointestinal streptococci species
Encapsulated bacteria
Viral
Herpes simplex virus
Cytomegalovirus
Varicella zoster virus
Respiratory and enteric viruses
(Seasonal/intermittent)
Other viruses eg. HHV
EBV PTLD
Fungal

Day 100
Day 365 and beyond

Figure 85.1 Phases of opportunistic infections among allogeneic HCT recipients.

especially of subclass II, can be present, rendering patients vulnerable to severe infection by encapsulated bacteria.

By 1 year, immune recovery is nearly complete in recipients of matched-related transplants without GVHD and off immunosuppressive medications. However, in matched unrelated donor and mismatched family-related donor transplants, immune recovery may lag substantially. Even in the absence of overt GVHD, vulnerability to recurrent sinopulmonary infections can persist for much longer periods than for those seen after HCT using grafts from HLA-matched siblings [15]. Responses to immunizations may be impaired up to 1 year or longer.

Spectrum of bacterial infections

Just as the defects in host immunity vary over time, so does the spectrum of infections. In Figure 85.1, the various infectious syndromes that occur at different times after HCT are portrayed [6]. As noted previously, relative to viral and fungal infections, bacterial infections predominate during the early recovery phase, whereas viral and fungal infections predominate during the mid- and late recovery phases. However, there are important differences that vary over time, as noted in Tables 85.5 and 85.6.

Early recovery (phase I)

Among neutropenic patients with fever, approximately 50% will have an infection that can be documented, and in the remainder no cause can be definitively identified. Because signs and symptoms of infection are attenuated during neutropenia, and untreated bacterial infections may be rapidly life threatening, neutropenic fevers should operationally be regarded as infectious until proven otherwise.

Bacterial pathogens account for more than 90% of the first infections during neutropenia. Gram-negative bacteria are the most virulent bacterial pathogens during neutropenia, and historically have been major causes of morbidity and mortality. Over the past 25 years,

Table 85.5 Bacterial and fungal infectious syndromes encountered early after hematopoietic cell transplantation (HCT), during the pre-engraftment phase (early recovery or phase I)

Syndrome	Relative frequency[a]	Relative life-threatening potential
First fever		
Staphylococci		
Staphylococcus epidermidis	+++	+
Staphylococcus aureus	+	+++
α-Hemolytic streptococci	+	++
Gram-negative bacilli	+	+++
Subsequent fevers		
Antibiotic-resistant Gram-negative bacilli	+	+++
Staphylococci		
Staphylococcus epidermidis	+++	+
Staphylococcus aureus	+	+++
Fungi	++	+++

GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation.

the percentage of infections caused by Gram-negative organisms has steadily decreased from 70 to 30%. However, over the past decade several centers have reported an increase in the proportion of Gram-negative bacterial infections [16,17]. The most common Gram-negative bacteria have been *E. coli*, *Klebsiella* spp., and *P. aeruginosa*. Several other organisms, such as *Acinetobacter* spp., *Stenotrophomonas* spp., *Alcaligenes xylosoxidans*, *Serratia* spp., *Legionella*, and *Burkholderia cepacia*, have also been increasingly identified [18]. The portal of entry for many organisms is the damaged mucosa of the gastrointestinal tract. Perianal fissures or skin breakdown are other potential sources, especially for *P. aeruginosa.* Occasionally, venous catheters can also serve as an entry site for Gram-negative bacteria.

Gram-positive bacteria have emerged as major pathogens, and bacteremia rates for Gram-positive organisms now exceed those for Gram-negative bacteria [16–18]. Gram-positive bacteria currently account for 70% of bacterial infections, compared with 30% 30 years ago. This increase is in large part attributable to the nearly universal use of indwelling CVCs. The widespread use of antibiotics with Gram-negative coverage to decontaminate the gut and reduce Gram-negative infections has also contributed to the proliferation of Gram-positive infections. Occasionally, Gram-positive organisms may also invade the host via the gastrointestinal tract. *S. epidermidis*, *S. aureus*, α-hemolytic streptococci, and enterococci are the most common organisms [19].

The portal of entry for α-hemolytic streptococci is frequently a breach in the oral mucosa. Thus, patients with stomatitis due to chemotherapy or radiotherapy, or with HSV-induced mucosal ulcerations, are particularly at risk. Several large series have reported bacteremia rates of 15–25% in HCT populations [20–23]. Where speciated, *Streptococcus mitis*, an organism that normally resides on the buccal mucosa, is the most common α-hemolytic *Streptococcus*. Although Gram-positive bacteria are less virulent than Gram-negative bacteria, approximately 10% of α-hemolytic streptococcal bacteremias are associated with a toxic shock-like syndrome that can be fatal even with prompt antimicrobial therapy [21,22,24]. The use of fluoroquinolones in several series has been associated with an increased risk for streptococcal infection [25,26]. *Corynebacterium jeikeium* infections are associated with infected marrow needle puncture sites or infected peripheral venous catheters, often with associated thrombophlebitis. Typically, they are resistant to multiple antibiotics and frequently require catheter removal [27].

After institution of antibiotics during first fever, the microbial flora changes. Superinfections, as manifest by recurrent or persistent fever during the second or subsequent week of neutropenia, are more heterogeneous in etiology (Table 85.5). Gram-negative bacteria, especially those that are resistant to the antibiotic regimen used to treat the first febrile episode, are of paramount concern [28]. These bacteria account for only roughly 10% of superinfections, but are highly virulent and have rapid life-threatening potential if appropriate antibiotic modification is not made.

The most common etiologic pathogen for bloodstream infections is *S. epidermidis*, which accounts for roughly half of superinfections. These organisms are less virulent than Gram-negative bacteria and are quickly isolated from blood cultures of bacteremic patients. Hence clinicians can wait until multiple blood cultures are positive to ensure that the isolate is a true pathogen rather than a harmless contaminant (operationally defined as a single positive culture). Less common is *S. aureus*; however, *S. aureus* is highly virulent, and requires prompt and vigorous antibiotic treatment. Other potential causes of superinfection include fungal pathogens and *Clostridium difficile*-associated diarrhea (CDAD).

Table 85.7 Causes of fevers of obscure origin after engraftment during mid- and late recovery (phases II and III)

Cytomegalovirus
Central venous catheter infections
Occult sinusitis
Hepatosplenic candidiasis
Pulmonary or disseminated *Aspergillus* infection

Mid-recovery (phase II)

With recovery of the neutrophil count, most bacterial infections resolve and antimicrobial agents can be discontinued. Fever of obscure etiology is occasionally noted in the mid-recovery period (Table 85.7). Sinusitis is a common cause of fever of uncertain etiology during this period [29]. Frequently, it occurs without specific focal signs or symptoms, but can readily be detected by either radiographs or computed tomography (CT) scans of the sinuses [30], and further investigated by nasal endoscopy. Another potential cause of fever is an occult infection of the CVC. Blood cultures are helpful but may be unrevealing initially. Removal of the catheter is occasionally required to exclude this possibility in a patient with persistent obscure fever, and is discussed under treatment of intravascular catheter-related infections.

Patients who have undergone allogeneic HCT are more susceptible to infections during the mid-recovery period than are autograft recipients [31], particularly if acute GVHD occurs and more intensive immunosuppression is necessary (Table 85.6). Although viral and fungal infections predominate during this period, occasionally Gram-negative bacteremias can occur as a result of disruption of the gastrointestinal mucosa barrier from acute GVHD. Also, Gram-positive bacteremia frequently occurs related to infections associated with the CVCs [19,32].

Late recovery (phase III)

Over time, with gradual immune recovery, the risk for infection progressively declines. Autograft recipients have a very low risk for bacterial infection late after the procedure. If the indwelling CVC remains in place, however, infections associated with the catheter can continue to occur, especially if the catheter continues to be used or if fibrin sheaths develop. In the absence of cGVHD, allogeneic transplant recipients have a progressively declining risk for bacterial infection. However, patients with cGVHD are highly susceptible to recurrent bacterial infections, especially from encapsulated bacteria, including *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Neisseria meningitidis*, due to low CD4 lymphocyte counts, poor reticuloendothelial function, and low levels of opsonizing antibodies [14,15,33,34]. The continuing use of immunosuppressive therapy, especially corticosteroids, with their deleterious effects on phagocytosis, renders the patient susceptible to recurrent infection. As noted earlier, patients who are the recipients of mismatched or matched unrelated donor transplants are, even in the absence of cGVHD, vulnerable to recurrent infections [15], especially sinopulmonary infections.

Treatment strategies

First fever during neutropenia

With the recognition that most febrile episodes during neutropenia are infectious in origin, awareness of their life-threatening potential, and knowledge that most first infections are due to bacteria, evaluation should be prompt and thorough. Special attention should be directed to the oral cavity, skin, lung, catheter sites, and perianal area. Cultures of suspected sites of infection should be obtained, and in all patients at least two sets of blood samples should be submitted for bacterial and fungal cultures. Each set consists of an aerobic and anaerobic blood culture bottle. Patients with respiratory signs or symptoms should have a chest X-ray in addition to physical examination and routine blood cultures. Patients with signs and symptoms of a urinary tract infection or an abnormal urinalysis should have a clean catch urine specimen sent for analysis and culture.

Two or three blood cultures should be obtained either simultaneously or separated by 30–60 minutes [35]. According to the Infectious Diseases Society of America (IDSA) guidelines for the management of febrile neutropenia, at least one of these cultures should be from a peripheral venous puncture, and the other can be from an intravenous line [36]. Many centers do not draw peripheral blood cultures, preferring to draw two sets of cultures from the indwelling catheter. There appears to be no value in obtaining more than a single set of cultures per 24-hour period for patients with neutropenic fever. Preferably 20–30 mL per culture set for an adult is recommended [37], with proportionately smaller volumes for children: 1–2 mL blood per culture for neonates, 2–3 mL for infants aged 1 month to 2 years, 3–5 mL for older children, and 10–20 mL for adolescents are recommended.

Numerous satisfactory manual or instrumental culture systems are commercially available (reviewed in [35]). Most systems perform well, but no one medium or system is capable of detecting all microorganisms. Several systems are suitable for special considerations. There are products to minimize the inhibitory influence of antibiotics for patients who are already receiving antibiotics, and systems that are useful for detecting filamentous fungi or mycobacteria (such as the lysis centrifugation system). A recent technique, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOFMS) is speeding the ability to identify rapidly (within minutes) the organisms at the species level from colonies grown in cultures and also some antibiotic resistance phenotypic patterns (reviewed in [38]). Each technique has its strengths and shortcomings. In general, it is advisable that each transplant team meets periodically with the director of the hospital microbiology laboratory to review the blood culture system in place at that institution and the infections encountered in the HCT patients, in order to accommodate specific situations where special media would be advisable.

After evaluation, antibacterial agents should be instituted promptly on an empirical basis [36]. This strategy has reduced the morbidity and mortality associated with infection from more than 50% to less than 10% in the last 30 years, and has become universally adopted as the standard of care for management of the initial fever during neutropenia. A variety of antibiotic regimens have been evaluated in controlled clinical trials. It remains debatable as to whether one regimen is superior to another. What is generally agreed upon, however, is that antibiotics should be begun promptly at the first sign of fever, without waiting for isolation of an organism in blood or other cultures, even in the absence of signs or symptoms of infection, since the host is unable to mount an effective inflammatory response.

When choosing an antibiotic, a number of factors must be considered, such as the local susceptibility patterns, and also the susceptibility of organisms to available antibiotics. Other important considerations include toxicity of the individual agents (particularly in individuals with impaired organ function), allergy history (severity of allergy and class of agent that caused the allergy previously), the likelihood of the emergence of drug resistance, the risk for superinfection (both the frequency and the type of superinfection), and cost. A consensus committee of the IDSA first provided guidelines for the management of fever during neutropenia in 1990; these were updated in 1997, 2002, and 2010 [36]. Although developed primarily for hospitalized patients with neutropenia following conventional chemotherapy, they have been updated to include outpatient management of febrile neutropenia and are also suitable for HCT patients. These guidelines are evidence based, ranking both the strength and the quality of evidence of each recommendation.

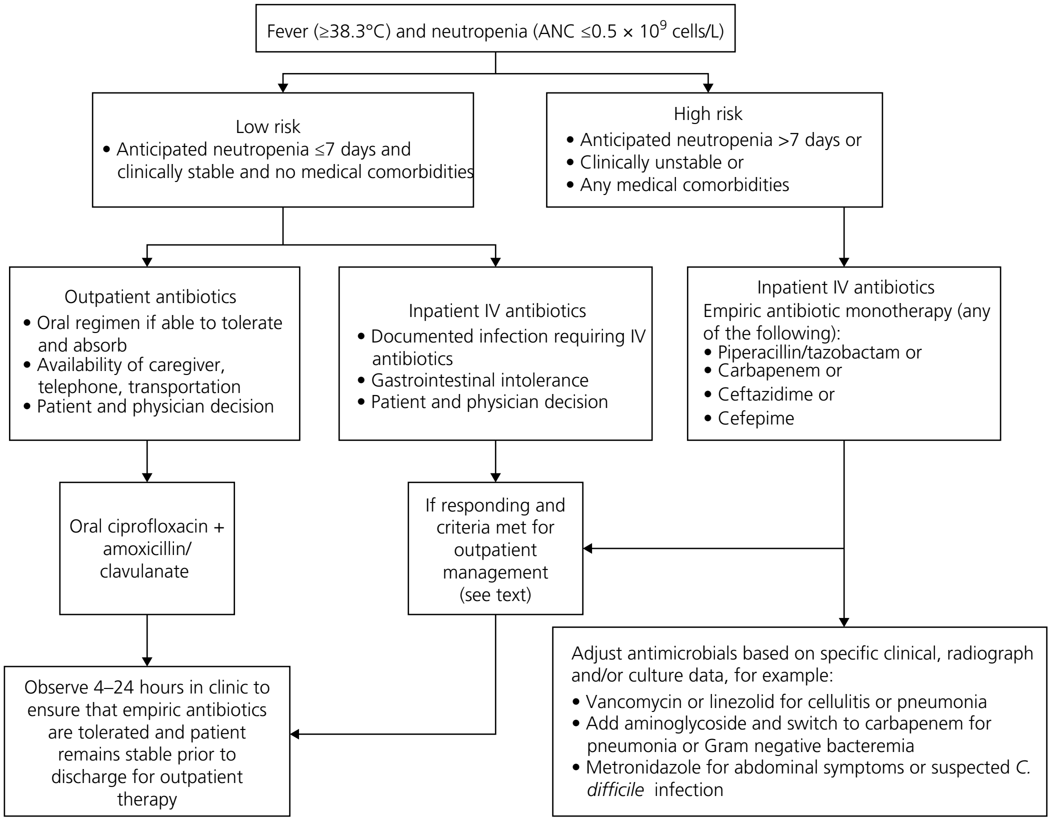
The IDSA's suggested strategies for first fever are indicated in Figure 85.2 [36]. The first decision concerns risk assessment at first fever. Patients categorized as low risk are those expected to have a short duration of neutropenia (<7 days) or to have no or few comorbidities. High-risk patients are those expected to have prolonged (>7 days) profound ($\leq 100/\text{mm}^3$) neutropenia and/or to have comorbid conditions that include hemodynamic instability, new pulmonary infiltrates, new-onset abdominal pain, oral or gastrointestinal mucositis that interferes with swallowing or causes severe diarrhea, or neurologic or mental status changes [36]. In general, the risk-status defines where the patient will be managed – inpatient or outpatient. With the increasing role of RIC regimens followed by HCT and rapid recovery seen with autologous peripheral blood cell transplants, some HCT patients are managed exclusively as outpatients and could be appropriately managed using the "low-risk" pathway in Figure 85.2. Indications and candidates for the outpatient management of febrile neutropenia are discussed under patient management of neutropenia.

High-risk patients

In high-risk hospitalized individuals with bacteremia, the choice of antibiotic should provide adequate coverage against *Pseudomonas aeruginosa* and other Gram-negative pathogens. The primary strategy in the absence of known drug-resistant Gram-negative pathogens, hypotension, or pneumonia is treatment with a single-agent broad-spectrum antibiotic, or monotherapy [36]. Successfully studied agents include the third-generation cephalosporin ceftazidime [39–43], the fourth-generation cephalosporin cefepime [41,42,44–51], the antipseudomonal penicillin piperacillin–tazobactam [44,47,52–54], and carbapenems including imipenem [40,44,48,49] and meropenem [55,56]. A number of studies have compared the outcomes of monotherapy with those achieved with combination therapy in the management of neutropenic fever. The majority of studies, including several meta-analyses, have not demonstrated any difference in outcomes between the approaches [57–60]. A meta-analysis of monotherapy versus combination therapy demonstrated lower rates of bacterial superinfection and fewer treatment failures among the monotherapy recipients [59].

Disadvantages of monotherapy include limited Gram-positive activity, particularly with ceftazidime, and lack of efficacy against viridans streptococci. Cefepime and the carbapenems have excellent activity against viridans streptococci and pneumococci. None, however, has activity against MRSA, which must be considered in hospitals with high MRSA rates. Other organisms that are poorly covered by monotherapy include vancomycin-resistant enterococci (VREs), penicillin-resistant *S. pneumoniae*, coagulase-negative *S. aureus*, ESBL-producing organisms, and carbapenemase-producing *P. aeruginosa* bacteria.

In the era of increasing bacterial resistance to antimicrobial agents, particularly VREs, clinicians need to implement strategies to reduce unnecessary antibiotic consumption. Cefepime in particular has reduced the need for the addition of vancomycin to the



Fever (≥38.3°C) and neutropenia (ANC ≤0.5 × 10⁹ cells/L)
Low risk
• Anticipated neutropenia ≤7 days and clinically stable and no medical comorbidities
High risk
• Anticipated neutropenia >7 days or
• Clinically unstable or
• Any medical comorbidities
Outpatient antibiotics
• Oral regimen if able to tolerate and absorb
• Availability of caregiver, telephone, transportation
• Patient and physician decision
Inpatient IV antibiotics
• Documented infection requiring IV antibiotics
• Gastrointestinal intolerance
• Patient and physician decision
Inpatient IV antibiotics
Empiric antibiotic monotherapy (any of the following):
• Piperacillin/tazobactam or
• Carbapenem or
• Ceftazidime or
• Cefepime
Oral ciprofloxacin + amoxicillin/ clavulanate
If responding and criteria met for outpatient management (see text)
Adjust antimicrobials based on specific clinical, radiograph and/or culture data, for example:
• Vancomycin or linezolid for cellulitis or pneumonia
• Add aminoglycoside and switch to carbapenem for pneumonia or Gram negative bacteremia
• Metronidazole for abdominal symptoms or suspected C. difficile infection
Observe 4–24 hours in clinic to ensure that empiric antibiotics are tolerated and patient remains stable prior to discharge for outpatient therapy

Figure 85.2 Algorithm for initial management of febrile neutropenic patients. Source: Youssef et al. 2007 [34]. Reproduced with permission of Elsevier.

empirical regimen when compared with ceftazidime [61]. In one study, vancomycin was added to the empirical regimen in 51% and 80% of cases, respectively [62]. When appropriateness of vancomycin use was evaluated against IDSA guidelines, patients receiving cefepime had less inappropriate use compared with ceftazidime patients (28% versus 58%; $p < 0.001$) [62]. One of the main concerns of monotherapy is the emergence of antimicrobial resistance. ESBL-producing organisms have been shown to reduce the utility of ceftazidime monotherapy [63,64]. Fourth-generation cephalosporins have not been subject to the same problem, and in fact ceftazidime-resistant strains of *Enterobacter cloacae* remain susceptible to cefepime [64]. Some institutions that have adopted an "antibiotic cycling" program, or have changed their preference of cephalosporin from ceftazidime to cefepime, have seen a reversal in the resistance patterns to ceftazidime of inducible Enterobacteriaceae [65].

Imipenem and meropenem have also been extensively evaluated in the management of febrile neutropenia [40,44,48,49,55,56]. In trials comparing carbapenems with third- and fourth-generation cephalosporins, there were no appreciable differences in time to recrudescence of fever, days of therapy, or breakthrough infections. One potential concern with the routine use of carbapenems is the lack of coverage against *Stenotrophomonas maltophilia*, an organism that is increasingly isolated in HCT patients. Depending upon individual institutions' susceptibility patterns, carbapenems are a suitable choice for monotherapy. Piperacillin–tazobactam has also been evaluated in the empirical treatment of neutropenic fever. Several studies have demonstrated efficacy comparable to or better than that with other broad-spectrum antibacterials such as cefepime [44,47,52,53]. The most recent large randomized trial demonstrated non-inferiority compared with cefepime among patients with hematologic malignancies or undergoing autologous HCT, leading to the addition of piperacillin–tazobactam to the current IDSA guidelines for the management of neutropenic fever [36]. Among patients with documented penicillin or cephalosporin allergies, suitable alternatives include ciprofloxacin plus clindamycin or aztreonam plus vancomycin [36].

The other class of antibiotics that has been evaluated less extensively is the fluoroquinolones such as ciprofloxacin [66–68] and levofloxacin. Ciprofloxacin has been studied, with varying results. One potential concern is the development of resistance, based on its widespread prophylactic use as part of "gut decontamination." If a patient develops a fever while on an oral fluoroquinolone, changing to intravenous fluoroquinolone monotherapy is a poor choice since the cause of fever may be an organism not susceptible to fluoroquinolones.

In previous IDSA guidelines, two-drug combinations (aminoglycoside plus either an antispeudomonal penicillin, cefepime, ceftazidine, or carbapenem) were recommended as an initial treatment choice for the treatment of neutropenic fever. In general, the evidence suggests that two-drug combinations have similar response rates to monotherapy regimens but are associated with greater toxicity. As such, they are no longer recommended, except where antibiotic-resistant pathogens are prevalent or documented.

For patients at high risk for infections caused by antibiotic-resistant pathogens such as MRSA, VRE, ESBL-producing organisms, and KPCs, modification to the initial empirical treatment regimen should be considered, particularly when the patient's condition is unstable or there is a suspected and/or documented infection with these pathogens [36]. Previous infection and colonization with one of these organisms or treatment in a hospital with a high rate of endemicity are risk factors for infection. Modification to the initial empirical treatment is made according to the suspected pathogen. Where MRSA is suspected, the early addition of vancomycin, linezolid, or daptomycin can be considered. For suspected VRE, the early addition of linezolid or daptomycin is appropriate. Early treatment with a carbapenem is appropriate where ESBL-producing organisms are anticipated and the early use of polymyxin–colistin or tigecycline can be considered where there is a high rate of KPCs, as KPC-producing organisms are resistant to all β-lactams [36]. Routine evaluation of institutional antibiograms will help guide the need for changes to antibiotic management by tracking changes in infections pathogens and susceptibility profiles.

The addition of agents with Gram-positive activity, such as vancomycin, linezolid, or daptomycin, to the initial empirical antibiotic therapy for neutropenic fever is not recommended in the IDSA guidelines [36]. Although infections caused by Gram-positive pathogens are common in patients undergoing HCT, these infections rarely cause rapid clinical deterioration, and are easily controlled once they are identified. Although the concern about severe sepsis from alpha streptococci in patients with severe mucositis led some clinicians to advocate the use of vancomycin, the introduction of fluoroquinolones with some activity against Gram-positive organisms, such as levofloxacin, has reduced that concern and therefore does not justify routine addition of vancomycin. More importantly, there is also concern regarding the emergence of resistance pathogens, such as *Enterococcus* and *S. aureus*, if vancomycin is overused [69,70]. Certainly, the emergence of VRE in many centers has led to calls for restricted use of this drug from the CDC and multiple infectious disease committees [71]. VRE infections are discussed below. The role of glycopeptides as part of the empirical antibacterial strategy has been evaluated in three separate meta-analyses [70,72–74]. In these evaluations, the addition of a glycopeptide to the initial antibacterial regimen for febrile neutropenia did not result in differences in treatment failure or all-cause mortality, but was associated with an increase in adverse events. Inclusion of vancomycin in first-line therapy can be considered in a number of circumstances. Use outside these indications should be curtailed. When vancomycin is used, serum trough concentrations of >10 mg/L should be targeted as there is evidence that trough concentrations <10 mg/L in patients with proven *S. aureus* infection can produce strains that are VISA-like, and in some conditions higher trough concentrations i.e., >15 mg/L are preferred [75].

The role of linezolid as part of the initial treatment for neutropenic fever is unclear. Linezolid has demonstrated comparable efficacy to vancomycin when added to the initial empirical treatment of patients with febrile neutropenia with proven or suspected infection due to a Gram-positive pathogen [76]. Broad use of agents that are traditionally restricted to severe infections such as VRE is not wise, particularly as the development pipeline for new antibacterials is so limited. There are reports of linezolid-resistant coagulase-negative staphylococci and *S. aureus*, linked to increased linezolid utilization [77,78]. Further, linezolid is known to cause bone marrow suppression, a toxicity that is best avoided where possible in HCT recipients.

Tigecycline has not been systematically evaluated as part of the initial empirical treatment in febrile neutropenia patients, and as such cannot be recommended as part of the initial regimen. Similarly, daptomycin has not been evaluated as initial empirical treatment of febrile neutropenia. There are retrospective registry data for daptomycin in the treatment of documented Gram-positive infections in cancer patients [79].

Low-risk patients

Low-risk patients can receive antibiotics in either the outpatient or inpatient setting. Patients who have a caregiver and access to a telephone and transportation, and can absorb oral medications, can be prescribed oral antibiotics and discharged home, after taking the first doses of medication in the clinic/hospital and being observed for 4–24 hours [36], with close follow-up. Antibiotics of choice in this setting include a combination of oral ciprofloxacin with amoxicillin–clavulanate. Other choices that have been evaluated less rigorously include levofloxacin or ciprofloxacin monotherapy, or a combination of levofloxacin plus clindamycin [36]. If a patient has been taking prophylactic fluoroquinolones, they are not candidates for oral empirical treatment with a fluoroquinolone.

Antibiotic modification during neutropenia

The response to the initial antibiotic regimen dictates subsequent management decisions. If the patient defervesces and is culture negative, the initial regimen can be continued without modification until resolution of neutropenia [ANC ≥500/mm^3 and rising]. For patients who remain persistently febrile by day 2–4 after initial empirical therapy, the approach to treatment modification is based on the patients' risk category.

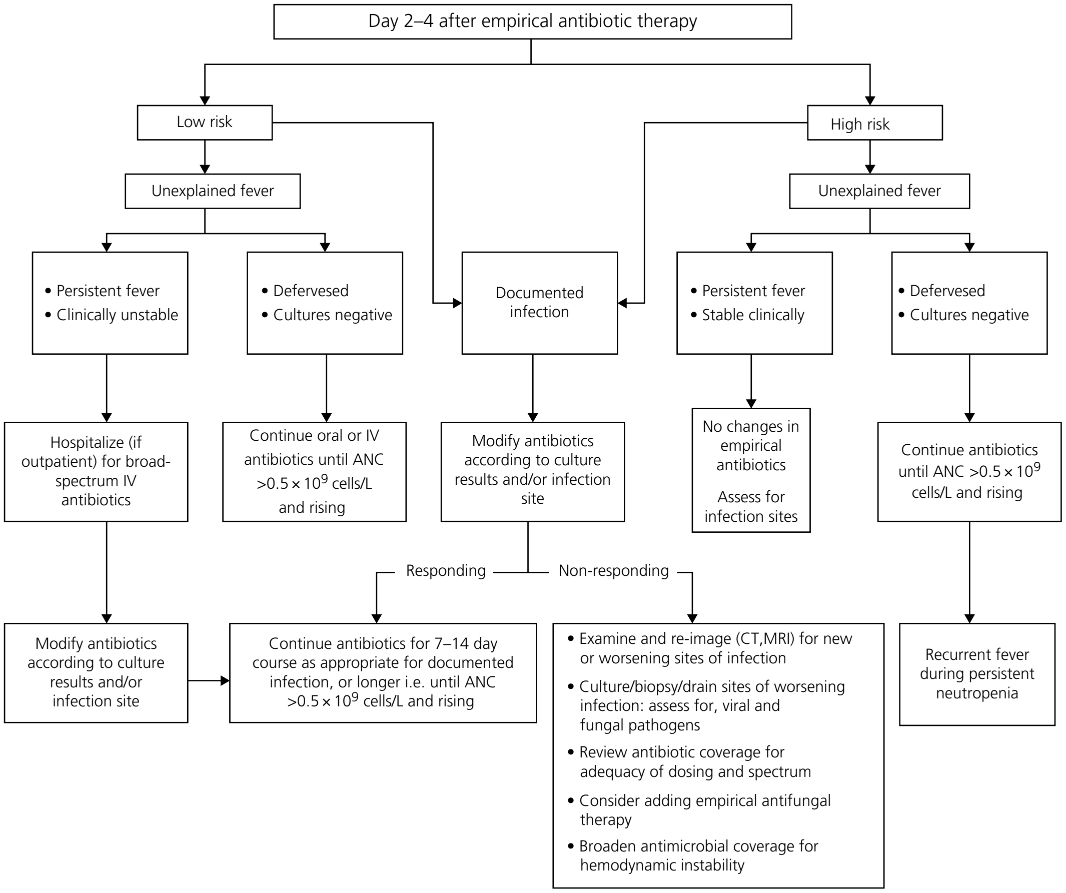
Low-risk (Figure 85.3) [36]

Low-risk culture-negative patients who are persistently febrile and are responding to the initial treatment regimen can continue on the initial treatment without modification until the ANC is >0.5 × 10^9/L. For those patients who started intravenous antibiotics, a transition to oral antibiotics can be considered if the gastrointestinal tract mucosa is intact and absorption can be assured. Low-risk culture-negative patients who remain persistently febrile and are clinically unstable should be hospitalized for broad-spectrum antibiotics. Antibiotic therapy should subsequently be modified according to culture results and/or the infection site. Antibiotics should be continued for 7–14 days for a documented infection, or longer, that is, until the ANC is >0.5 × 10^9/L and rising.

High-risk (Figure 85.4) [36]

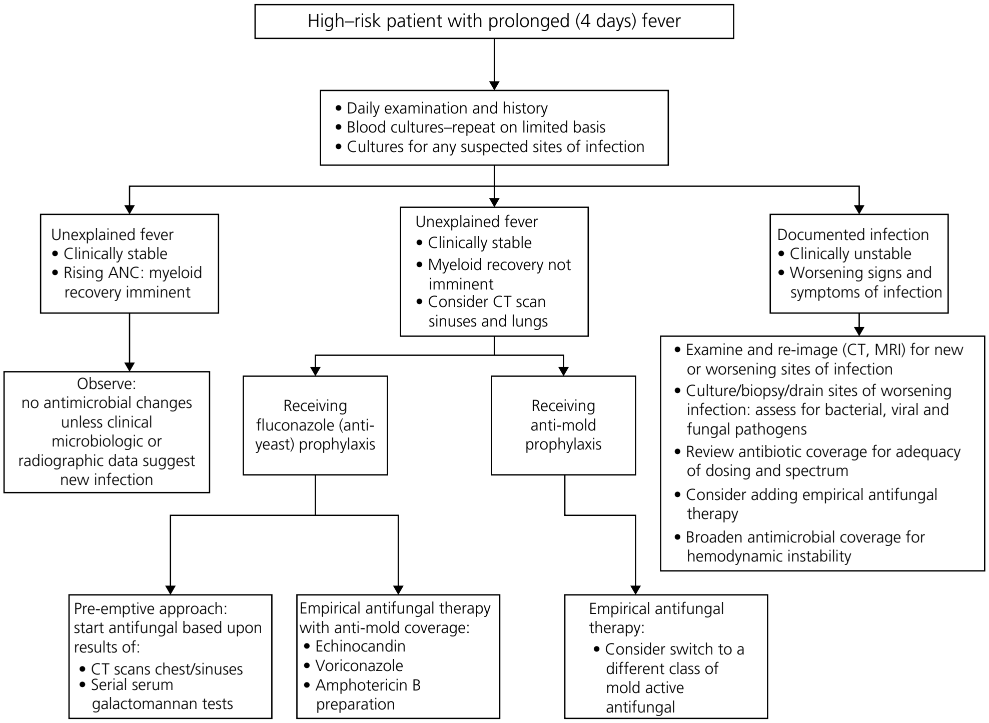
High-risk culture-negative patients who remain persistently febrile, but are stable clinically with no signs of progressive infection, should continue the initial therapy without modification. Antibiotic therapy should be continued until the ANC is >0.5 × 10^9/L and rising. For those patients in whom Gram-positive coverage was initiated as part of the initial treatment regimen, and remain culture negative, consideration should be given to stopping the Gram-positive therapy. High-risk culture-negative patients who are persistently febrile and hemodynamically unstable should be re-evaluated carefully. Consideration of drug-resistant pathogens should occur, and may necessitate a change in treatment based on local susceptibility patterns and resistance trends.

If fever persists or recurs five or more days after initiation of antibiotics and the patient is likely to remain profoundly neutropenic, the patient is at high risk for fungal infection (Figure 85.4). Consideration should be given to initiation of antifungal therapy, as discussed in Chapter 86, and the patient should be evaluated clinically and radiologically. Other causes of persistent or recurrent fever include *C. difficile*, neutropenic enterocolitis, another bacterial infection, or a non-infectious source. Provided that the patient is hemodynamically stable, continued fever alone should not prompt significant antibacterial modifications in the absence of positive culture data.



Day 2–4 after empirical antibiotic therapy
Low risk
High risk
Unexplained fever
Unexplained fever
• Persistent fever
• Clinically unstable
• Defervesed
• Cultures negative
Documented infection
• Persistent fever
• Stable clinically
• Defervesed
• Cultures negative
Hospitalize (if outpatient) for broad-spectrum IV antibiotics
Continue oral or IV antibiotics until ANC >0.5 × 10⁹ cells/L and rising
Modify antibiotics according to culture results and/or infection site
No changes in empirical antibiotics
Assess for infection sites
Continue antibiotics until ANC >0.5 × 10⁹ cells/L and rising
Responding
Non-responding
Modify antibiotics according to culture results and/or infection site
Continue antibiotics for 7–14 day course as appropriate for documented infection, or longer i.e. until ANC >0.5 × 10⁹ cells/L and rising
• Examine and re-image (CT,MRI) for new or worsening sites of infection
• Culture/biopsy/drain sites of worsening infection: assess for, viral and fungal pathogens
• Review antibiotic coverage for adequacy of dosing and spectrum
• Consider adding empirical antifungal therapy
• Broaden antimicrobial coverage for hemodynamic instability
Recurrent fever during persistent neutropenia

Figure 85.3 Guidelines for patient reassessment after 2–4 days of empirical antibiotic therapy. Source: Youssef et al. 2007 [34]. Reproduced with permission of Elsevier.



High–risk patient with prolonged (4 days) fever
• Daily examination and history
• Blood cultures–repeat on limited basis
• Cultures for any suspected sites of infection
Unexplained fever
• Clinically stable
• Rising ANC: myeloid recovery imminent
Unexplained fever
• Clinically stable
• Myeloid recovery not imminent
• Consider CT scan sinuses and lungs
Documented infection
• Clinically unstable
• Worsening signs and symptoms of infection
Observe: no antimicrobial changes unless clinical microbiologic or radiographic data suggest new infection
Receiving fluconazole (anti-yeast) prophylaxis
Receiving anti-mold prophylaxis
• Examine and re-image (CT, MRI) for new or worsening sites of infection
• Culture/biopsy/drain sites of worsening infection: assess for bacterial, viral and fungal pathogens
• Review antibiotic coverage for adequacy of dosing and spectrum
• Consider adding empirical antifungal therapy
• Broaden antimicrobial coverage for hemodynamic instability
Pre-emptive approach: start antifungal based upon results of:
• CT scans chest/sinuses
• Serial serum galactomannan tests
Empirical antifungal therapy with anti-mold coverage:
• Echinocandin
• Voriconazole
• Amphotericin B preparation
Empirical antifungal therapy:
• Consider switch to a different class of mold active antifungal

Figure 85.4 Algorithm for high-risk patients with persistent fever after 4 days of empirical antibiotic treatment. Source: Youssef et al. 2007 [34]. Reproduced with permission of Elsevier.

Where an infection has been documented, regardless of risk category, therapy targeted against the pathogens should be instituted. If signs of progressive infection occur, the patient should be re-evaluated, including examination and reimaging (CT or magnetic resonance imaging) for new or worsening sites of infection, culture/biopsy/drain sites of worsening infection, review of antibiotic coverage for dosing adequacy and appropriateness of coverage, consideration of adding empirical antifungal therapy, and broadening of antimicrobial coverage for hemodynamic instability (Figures 85.3 and 85.4) [36].

Fever following resolution of neutropenia

In the HCT population, patients occasionally remain febrile following neutrophil recovery. In this febrile, non-neutropenic population, where reassessment for undiagnosed infection is negative, antibiotics can be stopped after 4–5 days of an ANC over 500/mm^3, while evaluation to determine the cause of the fever is pursued. A common cause of fever that appears at the time of engraftment is the non-infectious entity known as engraftment syndrome.

Outpatient management of neutropenia

In recent years, a variety of considerations have led to the development of outpatient antibiotic regimens including the development of programmable infusion pumps, the widespread availability of home-care services, the desire for patients to receive more of their care in the outpatient setting, the introduction of highly effective and non-toxic antibiotic regimens, and an emphasis on cost containment. A variety of studies have identified factors that distinguish patients who are at low risk for serious morbidity from those who are at risk for septic shock and other complications of neutropenic fever [80–83]. Factors such as the presence of comorbid diseases, the development of fever as an inpatient, underlying hematologic malignancy, prolonged neutropenia (>10 days), and receipt of allogeneic HCT identify those at high risk. Low-risk patients include those with underlying solid tumors receiving conventional chemotherapy, those with a short anticipated duration of neutropenia (<7 days), and those with no comorbid conditions.

Following the stratification of the different clinical risk groups, further research has been centered on developing an internationally validated scoring system to identify low-risk patients at the onset of a febrile illness [82]. In a multivariate model, several characteristics have been identified that are considered independent predictive factors of favorable outcome. Integer weights were applied to these characteristics to develop a risk-index score, which was subsequently validated (Table 85.8) [82]. A risk-index score of 21 or more identified low-risk patients with a positive predictive value of 91%, a specificity of 68%, and a sensitivity of 71% [82]. This scoring system demonstrated lower misclassification rates and better sensitivity compared with earlier models. One of the limitations of the model is the applicability to the HCT setting. A small percentage of the patients studied were HCT recipients, but this model requires further validation in a larger cohort of transplant recipients. If applicable to this population, it could be possible to select low-risk patients for early intravenous-to-oral switch programs while remaining neutropenic.

Table 85.8 Scoring index for identification of low-risk febrile neutropenic patients at time of presentation with fever

Characteristic	Score[a]
Extent of illness[b]	
No symptoms	5
Mild symptoms	5
Moderate symptoms	3
No hypertension	5
No chronic obstructive pulmonary disease	4
Solid tumor or no fungal infection	4
No dehydration	3
Outpatient at onset of fever	3
Age <60 years[c]	2

[a] Highest theoretical score is 26. A risk index score of ≥21 indicates that the patient is likely to be at low risk for complications and morbidity. The scoring system is derived from the Multinational Association of Supportive Care in Cancer [82].

[b] Choose one item only.

[c] Does not apply to ≤16 years of age.

Outpatient antibiotic therapy or early discharge of patients at low risk for serious sequelae has been evaluated in non-HCT patient groups [80,83,84]. A meta-analysis of randomized trials evaluating the efficacy of oral versus intravenous antibacterials for the treatment of febrile neutropenia in low-risk cancer patients has demonstrated the safety and efficacy of oral antibiotics in this setting. Neutropenic patients who are low risk for mortality can safely receive oral antibiotics in lieu of hospitalization and intravenous administration [85]. Careful selection of suitable low-risk patients is imperative. Outpatient antibiotic regimens have also been evaluated in autologous HCT patients (neither of these is truly treatment, rather prophylaxis) and appear to be fairly promising for some HCT patients at low risk for serious sequelae. Stable febrile and neutropenic patients who are undergoing RIC regimens are also candidates for outpatient therapy. Close monitoring of such patients is imperative.

Vancomycin-resistant enterococci (VRE)

Enterococcal infections are the third most common cause of hospital-acquired bacteremia in hospitalized patients [86]. Importantly, the most recently published National Nosocomial Infections Surveillance system report demonstrated that 28.5% of enterococcal isolates are resistant to vancomycin [87], and large series in allogeneic HCT patients have demonstrated vancomycin resistance in enterococcal bloodstream isolates of 66% in adults and 31% in children [88]. *Enterococcus faecalis* and *E. faecium* are the most frequently identified species, with *E. faecium* being the most common VRE infection, and a smaller number being caused by *E. faecalis* and *E. avium* and other species. Of great concern is the development of resistance of *Enterococcus* to multiple antimicrobial agents. Enterococci are intrinsically resistant to certain β-lactams (particularly cephalosporins and penicillinase-resistant penicillin), low-concentration aminoglycosides, clindamycin, fluoroquinolones, and TMP–SMX. Acquired resistance to high concentrations of β-lactams and aminoglycosides, glycopeptides (vancomycin, teicoplanin), tetracycline, erythromycin, fluoroquinolones, rifampin, chloramphenicol, fusidic acid, and nitrofurantoin is also well documented [89]. More recently, the emergence of VRE with reduced susceptibility to new agents has been documented and is concerning.

There are six vancomycin-resistant enterococcal phenotypes, namely VanA, VanB, VanC, VanD, VanE, and VanG [89,90], of which VanA and VanB are the most common and clinically relevant. VanA resistance, characterized by acquired inducible resistance to high concentrations of vancomycin [minimum inhibitory concentration (MIC) 64–1000 μg/mL] and teicoplanin (MIC 16–512 μg/mL), can be induced by the presence of either drug. VanA resistance is mediated by transposon Tn1546. Of concern, high-level VanA vancomycin resistance has been transferred from *E. faecalis* to *S. aureus* via the Tn1546 transposon [91]. VanB-type resistance is characterized by acquired inducible resistance to low-to-high concentrations of vancomycin (MIC from 4 to over 1064 μg/mL), but sensitive to teicoplanin (MIC 0.25–2 μg/mL). Both VanA and VanB VRE phenotypes are most common amongst *E. faecium* and *E. faecalis*, and less common among other *Enterococcus* spp. such as *E. gallinarum* and *E. casseliflavus*, which are typically associated with the VanC phenotype [89–91].

Colonization and infection with VRE are a concern in high-risk neutropenic patients [92–95]. Colonization rates in patients undergoing HCT have been reported to be between 5.5 and 40% [85,93,96], and have increased almost threefold in recent series [88]. Up to one-third of these colonized patients develop VRE bacteremia, which is associated with high mortality rates [88,97,98]. Several risk factors have been identified that are associated with colonization or infection with VRE [89,90,99,100]. Antibiotic exposure, particularly to vancomycin, cephalosporins, and antianaerobic agents such as metronidazole and imipenem, are reported to increase risk [88,90,101]. Other variables that increase risk are a longer duration of hospitalization, greater severity of underlying illness, hemodialysis, receipt of corticosteroids, parenteral nutrition, neutropenia, mucositis, presence of feeding tubes, and a close proximity to colonized or infected patients. A recent evaluation of 750 allogeneic HCT patients identified several other risk factors for VRE bloodstream infection including colonization with VRE prior to HCT [risk ratio estimate (RRE) 3.3], colonization with VRE after HCT (RRE 7.7), acute GVHD grade III/IV (RRE 3.5), and delayed engraftment [88]. The percentage of patients who developed VRE bloodstream infections increased by each week delay in engraftment (4.5% if engraftment by day 21, 6.3% if engraftment by days 22–28, 11.9% if engraftment by days 29–35, and 15% if engraftment by days 36–42) [88].

Enterococci are resilient organisms and are able to be transmitted easily via healthcare workers, contaminated medical equipment, and also inadequately cleaned rooms following occupation with a VRE-positive patient. It is essential that standard infection control measures, as suggested by the CDC guidelines for preventing opportunistic infections in HCT recipients [6], be strictly adhered to [102]. These measures include either use of alcohol-based gels (preferred unless there is visible soiling of hands where hand washing is preferred) or hand washing with antibacterial soap before and after entering HCT patient rooms, and disinfecting patient rooms and equipment, including structural surfaces (e.g. walls, floors, and bed frames) with an approved US Food and Drug Administration (FDA) or Environmental Protection Agency-registered disinfectant [6,102,103]. Patients must also be placed under contact precautions until all antibiotics are discontinued and three separate repeat cultures, each 1 week apart, are negative. The Healthcare Infection Control Practices Advisory Committee has published recommendations for the management of multidrug-resistant organisms in healthcare settings, which includes VRE [104]. These guidelines recommend the development and implementation of protocols to obtain active surveillance cultures from high-risk patients, including HCT candidates. Implementation of contact precautions from the time the surveillance cultures are sent pending the results is also recommended. Implementation of surveillance programs for MRSA and VRE appears necessary based on increasing infection rates across a number of institutions. Whether these guidelines can be easily implemented remains to be seen, with likely significant increases in resource consumption [103,104].

Initial treatment of VRE-infected patients includes draining any collections if present, which is less likely in severely neutropenic patients with an absence of neutrophils. All indwelling vascular access devices should be removed immediately. There are a number of drugs that have been used in the management of VRE infection with traditional approaches, including ampicillin, gentamicin, chloramphenicol [105], tetracycline, and nitrofurantoin [89]. Newer agents include quinupristin–dalfopristin [106–108], a combination of streptogrammins, linezolid, an oxazolidinone [108–114], tigecycline [112], and daptomycin [115–121], a cyclic lipopeptide, all of which have shown good response rates in VRE bacteremias. The new agents have not been prospectively compared in large studies for the treatment of bloodstream enterococcal infections.

Quinupristin–dalfopristin is approved by the FDA for the treatment of *E. faecium* infections. Clinical efficacy of quinupristin–dalfopristin was demonstrated against VRE infections in a prospective, noncomparative, emergency-use study. Clinical response rates of 69% were documented [122]. Despite the FDA indication, it is rarely used in clinical practice owing to limited activity against *E. faecalis* and an unfavorable side-effect profile that includes musculoskeletal adverse events.

Daptomycin, an agent with bactericidal activity against VRE, has been evaluated in several retrospective observational studies [114,117–121,123,124]. Treatment with daptomycin is associated with microbiological or clinical cures in 58–90% of patients. Most enterococcal isolates have MIC values of ≤2 mg/L, although there are a number of isolates with MICs ≥4 mg/L. Isolates with higher MICs may need to be treated with higher doses of daptomycin up to 12 mg/kg [125,126]. There are several reports of VRE with reduced susceptibility to daptomycin [127,128], although more than 99.5% of VRE isolates remained susceptible to daptomycin in surveillance studies [129]. Close attention to local susceptibility patters and antibiograms is essential to detect any changes and impact on the likelihood of a positive outcome.

Linezolid is also effective for the treatment of *E. faecium* infections, including concurrent bacteremia. It is a bacteriostatic against enterococci. Clinical and microbiological response rates of approximately 75 and 94%, respectively, have been observed [130]. Similar to the other new agents for the treatment of enterococci, there are several reports of reduced susceptibility of VRE isolates to linezolid [131–135]. Linezolid therapy has also been associated with hematologic toxicity, which limits longer courses of therapy [136,137], although some data suggest that it can be safely administered in the post-HCT timeframe [138].

The role of tigecycline as monotherapy in the treatment of enterococcal bloodstream infections is unclear owing to low serum concentrations at standard dosing and its bacteriostatic properties [112,139]. A phase III trial comparing tigecycline with vancomycin or linezolid for the treatment of VRE was limited by poor enrollment, and no conclusions on comparative efficacy can be drawn. Case reports of VRE infections resistant to tigecycline have also been reported [139–141].

Clostridium difficile-associated diarrhea (CDAD)

C. difficile, a Gram-positive, spore-forming, anaerobic bacillus, of endogenous or exogenous origin, can establish itself in the colon and proliferate. *C. difficile* infection results in a wide range of clinical conditions ranging from asymptomatic colonization to colitis and toxic megacolon. Approximately 1–19% of patients with *C. difficile* have severe disease resulting in colectomy, intensive care admission, or death [142]. The impact of CDAD on other complications in allogeneic HCT recipients was recently evaluated in a large epidemiologic study of approximately 1000 patients. The development of CDAD is associated with a risk for developing gastrointestinal GVHD and the presence of gastrointestinal GVHD is a risk factor for relapsed/recurrent CDAD [143].

C. difficile usually produces two toxins, toxin A and toxin B. Patients are classified as *C. difficile* positive when either toxin A or B is detected in the stool. There are several methods for detecting *C. difficile*, of which the toxin-specific enzyme-linked immunosorbent assay (ELISA) method is the most common. The ELISA test can detect both toxin A and B, or only toxin A, depending on the reagent used. Reagents that detect both toxin A and toxin B are preferred as a small number of cases (1–2%) of *C. difficile* involve strains of *C. difficile* that produce only toxin B. ELISA results in a relatively high false-negative rate [144] and, as a consequence, between 10 and 20% of patients need more than one stool sample to detect toxin. Good clinical practice involves sending multiple stool specimens (up to three), to increase the diagnostic yield by 5–10% [145]. The ELISA test has a sensitivity of 63–94% and a specificity of 75- 100% [146] and also has the advantage of a quick turnaround for results. A number of other tests have been used [including glutamate dehydrogenase, cell culture neutralization assays, anaerobic toxigenic culture, and real-time polymerase chain reaction (PCR)] [146–148], but many of these tests are less sensitive and take considerably longer to generate a result, delaying implementation of treatment (reviewed in [146]). More recently, laboratories have been adopting nucleic amplification tests (i.e. PCR) targeting *C. difficile* toxin. These tests are associated with high sensitivity and specificity [146,147]. Testing for *C. difficile* should only be performed on unformed diarrheal stool, the only exception being where ileus due to *C. difficile* is suspected [146].

In 2005, a hypervirulent epidemic strain of *C. difficile* was associated with a number of CDAD outbreaks in Canada, the United States, the United Kingdom, and Europe. This strain was associated with an increase in incidence of CDAD and also severity of the disease. The hypervirulent strain was identified as the North American Pulsed Field Type 1 (NAP1), restriction enzyme analysis type "B1," and PCR isotype 027 [149–152]. NAP1/B1/027 produces a binary toxin that is associated with more severe CDAD cases. The NAP1/B1/027 strain has an altered repressor gene, *tcdC*, which regulates toxin A and B production, resulting in 16–23-fold more toxin A and B than wild-type strains [149]. The presence of the NAP1/B1/027 strain is associated with a more severe disease course [152,153], increased relapse rates following conventional treatment [154,155], disease in uncommon populations [156,157], and a higher attributable mortality [152,158]. Most laboratories do not have capabilities to determine whether the *C. difficile* is the NAP1/B1/027 strain. Specimens can be sent to the CDC for testing. Today, the NAP1/B1/027 strain occurs relatively frequently, representing approximately one-third of patients in recent randomized clinical trials assessing a new treatment, and is more common in North America than Europe [159].

C. difficile has emerged as the most common cause of hospital-acquired diarrhea. *C. difficile* is thought to be the cause of 20–30% of all cases of antibiotic-associated diarrhea, and a higher percentage of colitis associated with antibiotic treatment [145,146]. Among HCT recipients, CDAD is reported to occur in 5–15% of patients with diarrhea [143,160–164]. The most widely recognized risk factor for the development of CDAD is antimicrobial therapy, an increased duration of therapy, the use of broad-spectrum antibacterials, and the use of multiple agents. Almost all antimicrobial agents have been associated with the development of CDAD, including clindamycin, penicillins, and cephalosporins. The fluoroquinolones emerged as a predominant risk factor for CDAD during an outbreak of NAP1/B1/027 CDAD in Canada [153]. Other risk factors for developing CDAD include older age, residence in a nursing home or long-term care facility, use of proton pump inhibitors [165,166], and contact with active carriers. In HCT recipients, risk factors for the development of CDAD include receipt of chemotherapy prior to HCT conditioning [143], TBI [164], receipt of cord blood stem cells [164], broad spectrum antibimicrobial use [143], VRE colonization [143], and acute graft-versus-host disease [143,164].

Where possible, treatment of CDAD involves discontinuation or streamlining of antibiotic therapy. Among HCT recipients, this is often not feasible owing to underlying infection. First-line treatment options for CDAD, as currently recommended by the Society for Healthcare Epidemiology of America (SHEA) and IDSA, include metronidazole and vancomycin, choice being dependent upon severity of disease [146]. Two older comparative trials [167,168], a recent systematic review [169], and a randomized trial demonstrated equivalent response rates in mild CDAD [170]. In severe cases of CDAD, vancomycin was associated with an improved response rate [170]. Failure rates associated with metronidazole therapy have increased from approximately 7% in the 1990s to 16–38% in more recent series [155,171]. No specific cases of metronidazole resistance have been documented in North America. Mild cases of CDAD should be treated with metronidazole 500 mg orally three times per day for 10–14 days [146]. It is significantly cheaper and is not associated with the VRE resistance issues that plague vancomycin therapy. If alternative treatment is necessary owing to intolerance or failure to respond to initial therapy, vancomycin 125 mg orally four times daily should be initiated. Severe cases of CDAD should be treated initially with vancomycin 125 mg orally four times per day for 10–14 days [146]. Severe cases are defined in the SHEA/IDSA guidelines as those with leukocytosis with a white blood cell (WBC) count of 15,000 cells/mL or higher or a serum creatinine level ≥1.5 times the premorbid level [146]. For those patients with severe complicated CDAD, defined as presence of hypotension or shock, the recommended treatment is vancomycin 500 mg orally four times per day plus metronidazole 500 mg intravenously every 8 hours. If an ileus is present, vancomycin can be administered rectally at a dose of 500 mg (diluted in 100 mL of normal saline) every 6 hours in addition to the oral/intravenous combinations listed previously [146].

Fidaxomicin, an oral non-absorbable macrocyclic antibiotic, was approved by the FDA for the treatment of CDAD in adults ≥18 years of age in 2011. The efficacy of fidaxomicin (200 mg orally twice daily) compared with vancomycin (125 mg orally four times daily) was evaluated in two large double-blind, non-inferiority, randomized studies, where the primary end-point was clinical cure, defined as resolution of diarrhea for the duration of treatment and no need for additional treatment up for 48 hours following treatment completion [159,172]. In both trials, the clinical cure rate was similar in both groups, as was time to resolution of diarrhea [159,172]. Recurrence of CDAD was more common among recipients of vancomycin compared with fidaxomicin, which translated into lower sustained responses with vancomycin in both trials [159,172]. A recent meta-analysis of these trials confirmed that fidaxomicin is superior to vancomycin in reducing CDAD recurrences [173]. In subgroup analyses, fidaxomicin appeared to be superior to vancomycin among patients who needed to continue concomitant antibiotics [159], patients ≥65 years of age [159,172], patients with severe CDAD [159,172], and patients infected with the non-027 strain of *C. difficile* [159,172]. Among patients infected with the hypervirulent NAP1/B1/027 strain, the efficacy of fidaxomicin was equivalent to that of vancomycin [159,172]. Fidaxomicin is well tolerated, with no differences in treatment-emergent adverse events compared with vancomycin. Despite the favorable efficacy and safety profile, the cost of fidaxomicin is prohibitive for widespread use. The cost of 10 days of therapy with fidaxomicin is approximately 125-fold higher than that with metronidazole and double that of vancomycin at standard doses. As a consequence, fidaxomicin is restricted in many institutions for use in patients who are known to be at high risk for CDAD recurrence or who have had multiple recurrent episodes of CDAD. SHEA/IDSA do not currently have recommendations for the use of fidaxomicin as their guidelines were published prior to FDA approval of fidaxomicin. Another approach is to take patients at high risk for developing a CDAD infection, and administer effective agents prophylactically. A phase IIIb trial to evaluate the safety and efficacy of fidaxomicin as prophylaxis against CDAD in adult HCT patients is currently enrolling to address this question.

Treatment failure in immunocompetent patients is often defined as failure to stop diarrhea after 4–5 days of therapy. This definition may not be applicable in immunocompromised patients, since neutropenic patients require a longer time to respond [174]. If clinical symptoms progress, alternative treatment options should be considered. Vancomycin must be administered orally, not intravenously. Oral therapy results in high concentrations in the stool, whereas intravenous therapy does not achieve therapeutic concentrations in the stool. If intravenous therapy is absolutely necessary, metronidazole can be administered intravenously, as bactericidal concentrations are achieved in the colon when administered via this route [146]. A recent study compared the efficacy of oral metronidazole, intravenous metronidazole, and oral vancomycin in hospitalized patients with mild CDAD [175]. Patients treated with intravenous metronidazole had the highest mortality rate, suggesting that intravenous metronidazole is inferior to oral metronidazole and oral vancomycin, and should not be recommended unless absolutely necessary [175].

Other treatment options that have been investigated for CDAD include tolevamer [176], rifaximin [177], nitazoxanide [178,179], tigecycline [180], and fusidic acid. Nitazoxanide has been compared with metronidazole for the treatment of CDAD, resulting in similar times to resolution of symptoms of colitis, similar complete response rates at the end of 7 days of treatment, and similar sustained clinical responses 31 days after starting treatment [178]. Tolevamer at two different dosage levels has been compared with oral vancomycin, resulting in similar times to resolution of diarrhea [176]. Tigecycline has been reported to be effective in the management of recurrent/refractory CDAD in several case reports, although there have been no large studies demonstrating its efficacy, hence it should be considered investigational in this setting at present [180]. Both fusidic acid and bacitracin have been used in the treatment of CDAD, with mixed success. Emergence of resistance limits their use.

Patients with CDAD should be treated with appropriate therapy for 10–14 days. Relapses are reported to occur following successful treatment in up to 25% of cases [145,155], and recent data suggest that the relapse rate in HCT recipients is comparable at 21.7% [143]. Relapses can be treated with another 10–14 days of therapy as used in the initial episode. Relapses are primarily due to reinfection with a new strain and are not associated with bacterial resistance [146], therefore the drug used for the initial infection can be used for the relapse. Current SHEA/IDSA recommendations include a slow, tapering schedule of oral vancomycin over a period of 6 weeks or, in appropriate candidates, intracolonic vancomycin. Use of metronidazole beyond the first recurrence is not recommended owing to the potential for cumulative neurotoxicity with long-term use [146]. The use of probiotic therapy to restore normal colonic fecal flora has also been investigated in non-immunocompromised individuals [181]. Administration of *Lactobacillus* or *Saccharomyces boulardii* is reported to protect against *C. difficile*-induced colitis. A recent meta-analysis of probiotics for the prevention of CDAD suggested that there is a role for probiotic therapy, as probiotics cause a large reduction in CDAD without any adverse events [181]. These approaches should be avoided in neutropenic patients owing to risk of active infection with the probiotic organism as opposed to colonic colonization. Finally, intravenous immunoglobulin (IVIg) therapy has been used with some success. The basis of decreasing transmission of *C. difficile* is good infection control. This is discussed later under preventive strategies.

Investigational approaches to the treatment and prevention of CDAD include fecal microbiota transplantation and the use of monoclonal antibodies to *C. difficile* toxin A and administration of antibodies specific to *C. difficile.* Preclinical studies suggest that such antibodies will augment the immune response to *C. difficile* toxins. A phase II randomized trial of two fully human monoclonal antibodies against *C. difficile* toxins A (CDA1) and toxin B (CDB1) has been completed. The trial demonstrated that infusion of CDA1 and CDA2, in conjunction with systemic therapy, reduced the rate of recurrence of CDAD and more specifically also reduced the recurrence of more virulent strains such as NAP1/BI.027 [182]. Phase III trials assessing the safety and efficacy of monoclonal antibodies against toxin A, toxin B, and toxin A and B are currently under way (MODIFY-1 and MODIFY-2). Fecal microbiota transplantation, a process whereby feces from a healthy donor are transplanted into the colon of a CDAD-infected patient, has demonstrated efficacy in several case series for the treatment of recurrent or refractory CDAD [183]. This approach is being evaluated in two randomized controlled trials, one of which, the Fecal therapy to Eliminate *Clostridium difficile* Associated Longstanding diarrhea (FECAL) study is completed and results are expected soon. The second trial, being conducted by investigators at the National Institutes of Health, was recently approved and will start enrollment in the near future. This approach has two limitations, the first being the willingness of patients to consider transplantation of feces from anther individual, and second the risk of disease transmission. Hence this approach is considered investigational and should be reserved for highly refractory cases. This approach has been used in non-neutropenic HCT candidates [184].

MRSA and CA-MRSA

Infections caused by MRSA are increasing, and not only nosocomially acquired but also community-acquired infections have been identified [185]. The MRSA strains found in the community are genetically different from strains typically found in healthcare facilities, resulting in subtle differences in clinical presentation and considerable differences in the antimicrobial susceptibility profile. Typical infections associated with healthcare-associated MRSA (HA-MRSA) strains include ventilator-associated pneumonia, surgical site infections, and central line-associated bloodstream infections. In contrast, community-acquired MRSA (CA-MRSA) strains primarily present as skin and soft tissue infections, but have been associated with more severe syndromes such as osteomyelitis and pneumonia [186,187]. There are also differences in antibacterial susceptibilities between HA-MRSA and CA-MRSA. HA-MRSA is not only resistant to penicillins, and other β-lactams, but is usually also resistant to other classes of drug, including fluoroquinolones, macrolides, and clindamycin. CA-MRSA, however, maintains susceptibility to fluoroquinolones, macrolides, clindamycin, tetracyclines, and TMP–SMX [188]. These issues need to be considered in HCT patients who move routinely between the inpatient and outpatient units. Historically, CA-MRSA has not been a concern, although it now should be part of the differential when patients are readmitted.

Vancomycin has been the reliable cornerstone of MRSA treatment for more than 20 years. Over the past few years, a number of vancomycin-intermediate *Staphylococcus aureus* (VISA) infections and vancomycin-resistant *S. aureus* infections have been reported, and the presence of VISA in the setting of complex infections has been underestimated [189]. Likewise, vancomycin failures in the absence of VISA and vancomycin-resistant *S. aureus* are increasingly reported [190]. In recognition of this information, the Clinical and Laboratory Standards Institute lowered the MIC interpretative criterion for *S. aureus* to 2 μg/mL to improve the likelihood of clinical success and improve resistance detection. In addition, adjustment of vancomycin dosing to achieve higher troughs is recommended in the vancomycin monitoring guidelines to minimize resistance selection and optimize clinical response for complicated infections [75]. Desired trough concentrations between 10 and 20 μg/mL are needed for most infections, and may be pushed to 15–20 mg/mL in complicated infections such as endocarditis and osteomyelitis. Despite these recommendations, data suggest that elevated vancomycin MICs (1–2 μg/mL) in concert with optimized vancomycin dosing may still result in treatment failure and in this setting combination therapy may be necessary, or even a change of therapy [191]. Of note, treatment failure occurs in both methicillin-susceptible *Staphylococcus aureus* (MSSA) and MRSA strains, suggesting there are other variables impacting patient outcomes beyond vancomycin therapy [192]. Owing to the complexity in managing MRSA infections, the IDSA developed a clinical guideline to assist clinicians with managing common clinical syndromes observed in MRSA infections (e.g. skin and soft tissue infections, central nervous system infections, bacteremia, pneumonia, endocarditis, abscesses), provide guidance for determining clinical response, define the role of alternate therapies, and address appropriate dosing [193].

The changing epidemiology of MRSA infections is concerning. CA-MRSA infections are being reported in healthcare facilities, and strains of MRSA typically associated with healthcare facilities are being reported in the community. Acute awareness of the change in infection patterns is necessary when selecting empirical treatment for HCT candidates. Likewise, the reduced efficacy of historically "workhorse" antibacterials must be considered among patients failing to clear infections. Alternatives to vancomycin, in the face of treatment failure, vary according to the type of infection. For MRSA bacteremia, daptomycin is the recommended alternative agent in a dose of at least 6 mg/kg/day, often increased to 8–10 mg/kg/day [193]. In contrast, patients with pneumonia should not receive daptomycin owing to inactivation by pulmonary surfactant, and instead linezolid (600 mg PO/IV twice daily) and clindamycin (600 mg PO/IV three times daily) are alternatives assuming susceptibility.

Neutropenic enterocolitis/typhilitis

Neutropenic enterocolitis (also known as typhilitis and necrotizing colitis) is a syndrome characterized by neutropenic fever (ANC <100/mm^3), abdominal pain (especially right lower quadrant pain), diarrhea, and radiographically observed bowel wall thickening [194,195]. Characteristic radiologic findings include one or more of the following: thickened bowel wall (>4 mm) with a predilection for the cecum, fluid-filled dilated bowel loops, right lower quadrant inflammatory mass, pericecal fluid or inflammatory changes in the pericecal soft tissues. Rebound tenderness may or may not be present. Neutropenic enterocolitis occurs in approximately 6% of adult patients receiving treatment for acute leukemia [194]. Pathologically, the structural integrity of the bowel wall is compromised, with microbial invasion, bowel wall necrosis, and edema; hemorrhage and perforation sometimes occur. Neutropenic enterocolitis has a high mortality rate. Recognition of clinical signs and symptoms, prompt evaluation, and institution of broad-spectrum antibacterial treatment (to cover Gram-negative and anaerobic bacteria) are imperative. In addition to bacteria, fungal organisms are often isolated, with *Candida* being the most common pathogen. Therefore, antifungal treatment with fluconazole, or another suitable azole, should be instituted in addition to antibacterial treatment [142].

Treatment of late bacterial infections

Recurrent sinopulmonary infections are frequently associated with cGVHD or immunoglobulin deficiency [6,14,15,33]. They can be treated successfully with a variety of antibiotics, including penicillin, macrolides, fluoroquinolones, and second-generation cephalosporins, depending on local susceptibility patterns [6]. If immunoglobulin deficiency is present (i.e. IgG <400 mg/dL), IVIg can be helpful [6], but it is very costly. An alternative strategy that can be considered is chronic antibiotic prophylaxis, but emergence of antibiotic resistance may limit the utility of such an approach.

Treatment of intravascular catheter-related infections

Intravascular catheters are used almost universally in HCT recipients. Tunneled CVCs such as Hickman, Broviac, and Groshong catheters, and also implantable devices such as the PortACath, are most commonly used. Peripherally inserted central catheter lines are also gaining greater use. The majority of infections are caused by Gram-positive organisms, particularly coagulase-negative *Staphylococcus*, and, less commonly, *S. aureus*, although Gram-negative infections with *Pseudomonas* spp., *A. baumannii*, and *Stenotrophomonas* spp. are increasingly documented.

The IDSA has developed, as mentioned previously, guidelines for the management of intravascular catheter-related infections [32], and these are useful in therapeutic decision-making processes. For those patients with a suspected CVC-related infection, the guidelines recommend that two sets of blood cultures should be drawn, with one set drawn percutaneously. This approach is most helpful if the blood sample drawn through the CVC is negative, as it excludes CVC-related infection. Once results identifying the organism are available, the choice of antibiotic therapy must be based on susceptibilities. Guidelines for managing tunneled CVC infections are outlined in Chapter 80 [36] and specifically address when to remove the catheter and the duration of antibiotic therapy. Patients should be educated on how best to access their lines if they are performing catheter care at home, to minimize the risk of catheter-associated infection. See Chapter 80 for further discussion of this topic.

Preventive strategies

General measures

The foremost principle of infection prophylaxis is minimization of the possibility that encounters with the healthcare team and exposure to the hospital environment place patients at greater risk for acquiring infection. Accordingly, clinical procedures, especially the placement of venous and urinary catheters, should be avoided when possible. General consensus guidelines for the prevention of infection in HCT patients have been published [6]. Hand hygiene with antiseptic gel (preferred with the exception of patients with *C. difficile* infection [6], or where there is considerable soiling of the hands) or washing by care providers is of utmost importance to avoid transmission of infectious agents from one patient to another or from staff to patients. Current guidelines recommend hand washing in the following circumstances: before and after direct contact with a patient; after contact with bodily fluids, non-intact skin, wound dressing; when moving from a contaminated to a clean body site during care of patients; where gloves are worn before and after placement of gloves [6]. Opinion is divided as to the need for decontaminating regimens to reduce the endogenous flora and the use of pathogen-free diets. However, abstinence from fresh fruits and vegetables is frequently advised, although studies have questioned the value of neutropenic diets [196,197].

Particular attention has been placed on the need for minimizing exposure to airborne organisms. Opinion again is divided as to the value of various isolation strategies. The consensus guidelines for the prevention of opportunistic infections in HCT recipients have recommended that all allogeneic HCT patients be placed in rooms with at least 12 or more air exchanges per hour and point-of-use high-efficiency particulate air (HEPA) filters capable of removing particles 0.3 μm or more in diameter be used [6]. The relative merits of laminar air flow versus HEPA-filtered rooms have not been established.

Knowledge that most infectious pathogens originate from the endogenous flora, and also the observations that in many instances these organisms are acquired after entry to the hospital environment, have led to investigation of the utility of bacterial and fungal surveillance cultures. Bacterial surveillance cultures have been found to be useful in detecting antibiotic-resistant bacteria [198]. Such surveillance culture programs have been useful primarily in the setting of prolonged neutropenia for detecting causes of superinfection. The disadvantages of routine use of surveillance cultures are the high cost, the enormous workload for the microbiology laboratories, and low predictive value [199]. Accordingly, routine surveillance of individual patients has not been used widely. Nevertheless, there is consensus that ongoing hospital-wide and unit-specific infection surveillance programs need to be in place to detect shifts in infectious pathogens and patterns of antibiotic resistance [198].

C. difficile is a major cause of diarrhea in HCT patients. Contaminated environmental surfaces and the hands of healthcare personnel are major sources of organism transmission to susceptible patients. Minimization of antibiotic exposure and attention to infection control measures to reduce person-to-person contact are of paramount importance in preventing outbreaks [200,201]. Most institutions utilize alcohol-based hand sanitizers for healthcare workers. Alcohol-based solutions do not effectively kill *C. difficile* spores; therefore, personnel should use soap (or antimicrobial soap) and water to wash their hands in units where there are infected patients. Healthcare personnel and visitors should use gloves and gowns when entering rooms of patients infected with *C. difficile*. Patients with CDAD should be isolated to a single room with contact precautions, and these contact precautions should be continued until the diarrhea has resolved [146]. Following patient discharge, the room should be cleaned with chlorine-containing agents or other sporicidal agents [146].

A variety of factors influence the risk for infection associated with CVCs: the type of catheter, site of insertion, catheter size, duration of use, degree of host immunodeficiency, type of precautions used during catheter insertion, and skill with which the catheter is inserted. The Hospital Infection Control Practices Advisory Committee has published guidelines for the prevention of infections related to intravascular devices [201]; these include training of the healthcare team that will place and maintain the lines, monitoring infection rates with different kinds of catheter over time, hand washing before and after handling catheters or their dressings, the use of barrier precautions during catheter insertion and care, the use of skin antiseptics before catheter insertion, the use of either sterile gauze or transparent dressings for covering the catheter site, change of dressings when they are soiled or wet, avoiding touching of the catheter exit site when the dressing is changed, the use of a single- rather than a multilumen catheter when possible, the use of a tunneled catheter if long-term use is anticipated, and the use of a subclavian rather than a jugular or femoral site unless necessary. Several controlled trials have evaluated the use of silver and antibiotic-impregnated catheters to reduce the risks for infection in non-HCT recipients [202–204]. This promising strategy was successful in the context of those clinical trials; however, the long-term effects in terms of antibiotic resistance are not known. Further, since the studies were not conducted with tunneled catheters, how applicable the results are to the HCT setting is yet to be tested.

Antibiotic prophylaxis during neutropenia

The frequency and severity of Gram-negative bacterial infections during neutropenia and concomitant gastrointestinal mucosal damage led to an early emphasis on suppressing the intestinal flora to prevent invasive infection. Early efforts to prevent bacterial infections employed the use of oral non-absorbable agents. Agents such as vancomycin, gentamicin, neomycin, colistin, and polymyxin B were advocated in various combinations. A variety of controlled trials have been conducted, and some have shown a beneficial effect. Unfortunately, difficulties with patient compliance, concerns about the emergence of resistance, the high cost of several of these regimens, and lack of evidence for a treatment effect on all-cause mortality and attributable mortality have led to poor acceptance. Interest in such regimens today remains, but due more to the potential for decreasing the elaboration of proinflammatory cytokines involved in the pathogenesis of GVHD than for infection control.

TMP–SMX has also been found to reduce both Gram-positive and Gram-negative bacterial infections in patients with hematologic malignancies and undergoing HCT [205,206]. Its broad-spectrum activity against a number of Gram-negative organisms is offset by its lack of activity against *P. aeruginosa*, a major pathogen in HCT patients. Moreover, concerns about delays in engraftment, patient tolerance, and selection of resistant organisms have limited its use. Because of these concerns and the paucity of data for HCT patients, this regimen has not been adopted widely.

The fluoroquinolones have been shown in controlled trials to reduce Gram-negative bacterial infections significantly, appear to be as or more effective than other oral antibiotic regimens, and have been evaluated in HCT patients [207,208]. Norfloxacin [209–212], ciprofloxacin [212–218], ofloxacin [219–221], perfloxacin [222,223], levofloxacin [224], and moxifloxacin [225] have been the most widely studied in HCT patients. Ciprofloxacin provides an advantage over norfloxacin in that oral administration achieves systemic blood levels; however, it is not active against most methicillin-resistant staphylococci (the majority of staphylococcal isolates). Levofloxacin offers greater activity against Gram-positive organisms, including *Staphylococcus* and *Streptococcus* spp., and therefore would be preferable to ciprofloxacin in patients expected to develop severe mucositis and at risk for streptococcal infections.

Concerns about the emergence of fluoroquinolone resistance have also been raised. The effect of fluoroquinolone prophylaxis on microbial resistance was addressed in a systematic review and meta-analysis of 56 randomized trials of antibiotic prophylaxis in neutropenic hosts [226]. Within the analysis, the trials were separated into two cohorts, namely those that compared fluoroquinolones with placebo/no intervention, and those that compared fluoroquinolones with other antibiotics. Many trials did not report colonization data, microbiological surveillance end-points, or routine susceptibility data. Of the fluoroquinolone versus placebo/no treatment trials reporting these end-points, there were no increases in colonization with organisms resistant to fluoroquinolones, and no difference in the proportion of patients developing infections caused by bacteria resistant to fluoroquinolones. Several microbiologically documented infections were observed in those trials, more of which were caused by fluoroquinolone-resistant organisms in the fluoroquinolone arm compared with placebo. A number of trials compared a fluoroquinolone with TMP–SMX. In those trials, fluoroquinolone use was associated with fewer fluoroquinolone-resistant bacteria in the fluoroquinolone arm than TMP–SMX-resistant bacteria in the TMP–SMX arm. Fewer fluoroquinolone-resistant infections were noted in the fluoroquinolone arm. That analysis demonstrated that there was no difference in the infection rate of fluoroquinolone-resistant pathogens when prophylactic fluoroquinolones were used. Limitations of the analysis were the small number of trials that reported colonization rates and microbiological surveillance results. Continued surveillance and analysis are necessary to evaluate local concerns.

The risk for streptococcal infections may also be greater among recipients of fluoroquinolone prophylaxis [26]. The addition of penicillin or rifampin to the fluoroquinolone can reduce the risk for streptococcal infection [216,227,228]. However, resistance to penicillin is also high in the community and it may not confer additional protection. Historically, preservation of the anaerobic flora has generally been believed to offer protection against more virulent pathogens. Little activity against anaerobes is a feature of the older quinolone, and this may be desirable in protecting against the more virulent pathogens.

Several groups have evaluated the role of antibiotic prophylaxis in neutropenic patients over the past two decades [207,208,229–233]. Early meta-analyses demonstrated that fluoroquinolones, although effective in preventing Gram-negative bacteremia, had no effect on days of fever or infection-related mortality [229,230]. Other analyses have similarly shown a reduction in the number of documented infections compared with placebo, particularly for Gram-negative pathogens [231,232]. Reduction in infection-related mortality due to bacterial causes has also been demonstrated [233]. More recently, a meta-analysis of 95 randomized clinical trials in 9283 afebrile neutropenic patients concluded that prophylactic antibiotics significantly reduced the risk for death compared with placebo or no treatment [relative risk (RR) 0.67, 95% confidence interval (CI) 0.55–0.81] [208,209]. Within the analysis, there were 55 trials that specifically addressed fluoroquinolone prophylaxis. Similar results were observed, with fluoroquinolone prophylaxis leading to decreases in all-cause mortality (RR 0.52, 95% CI 0.35–0.77) and infection-related mortality. Other important end-points including fever, and clinically and microbiologically documented infection rates, were also reduced.

The CDC/IDSA/American Society for Blood and Marrow Transplantation guidelines for the use of antimicrobial agents in neutropenic patients with cancer recommend the use of routine prophylactic quinolone therapy in this patient population only where the duration of neutropenia is anticipated to be 7 days or more [6].

Bacterial prophylaxis after engraftment

Morbidity and mortality from chronic GVHD are frequently due to infection. Antibiotic prophylaxis, although not providing universal protection against encapsulated organisms, substantially reduces the mortality from cGVHD [234,235]. Accordingly, all patients with cGVHD should be placed on daily antibiotic prophylaxis with penicillin, TMP–SMX or a suitable alternative guided by local susceptibility patterns for at least as long as active GVHD therapy is prescribed [6]. The host deficits that mediate vulnerability for infection persist even after successful completion of GVHD therapy and some centers continue antibiotic coverage longer, but duration of need has not been adequately studied. If penicillin is used, additional prophylaxis for *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) should also be administered. Even in the absence of cGVHD, patients with recurrent sinopulmonary infections and autografted recipients undergoing HCT with TBI-containing regimens [235] should be considered for prophylaxis to prevent infection from encapsulated organisms. Agents such as penicillin, cefaclor, cefuroxime, TMP–SMX, and the new-generation macrolides are particularly useful. Moreover, patients who have previously undergone splenectomy should be considered for antibiotic prophylaxis against encapsulated bacteria.

Adjunctive measures

Growth factors

Growth factors such as granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF) to stimulate more rapid hematopoietic recovery, and to obtain an enriched hematopoietic cell product, have become widespread in the field of HCT, and are especially useful in autologous HCT (see Chapter 43). Unfortunately, although neutrophil recovery is hastened in most prospective randomized trials, the effects on preventing bacterial infections have been either nonexistent or marginal.

A meta-analysis of 34 randomized controlled trials of prophylactic G-CSF and GM-CSF demonstrated that colony-stimulating factors were associated with a small reduction in the risk of documented infections (RR 0.87, 95% CI 0.76 – 1.00, $p = 0.05$), with an absolute decrease in the risk of documented infection of 8%, which did not translate into improved infection rates or treatment-related mortality [236]. The meta-analysis included a number of subgroup analyses including differences between colony-stimulating factors, that is, G-CSF versus GM-CSF, and also differences between transplant types, that is, autologous versus allogeneic HCT. In those analyses, there was no difference in documented infections in trials that utilized G-CSF, whereas a benefit was demonstrated for

GM-CSF. There was no advantage to colony-stimulating factor use in the autologous HCT setting, whereas there was a significant reduction in documented infections among allogeneic recipients receiving colony-stimulating factors. Other outcomes that were evaluated included microbiologically and clinically documented infection, days of fever, days of parenteral antibiotics, and infection-related mortality. There was no difference in microbiologically documented infection regardless of analysis type. Clinically documented infection was no different among the groups analyzed. Days of fever were not statistically different in the overall analysis and in the G-CSF recipients, whereas GM-CSF recipients had fewer days of fever. There were fewer days of parenteral antibacterials administered in all analyzed groups with the exception of allogeneic HCT recipients [236]. Finally, infection-related mortality did not differ in any of the groups analyzed. Therefore, the benefit of colony-stimulating factors on documented infection and associated complications is small and should be weighed against the cost of these agents.

Current consensus guidelines from the American Society of Clinical Oncology (ASCO) recommend colony-stimulating factors following autologous HCT and not following allogeneic HCT [237]. Of interest is the use of hematopoietic growth factors as an adjunct to antibiotic therapy for established infection or for patients with persistent fever. However, controlled trials have failed to show improved outcomes in either HCT or non-HCT neutropenic patients other than shortening of neutropenia duration, antibiotic utilization, and hospitalization. The current ASCO guidelines do not recommend the routine use of colony-stimulating factors as adjunctive treatment with antibiotic therapy in patients with febrile neutropenia. The exception to this recommendation is in patients who are at high risk for infection-associated complications or those patients who are likely to have a poor clinical outcome based on known prognostic factors such as prolonged and profound neutropenia (>10 days and ANC $<0.1 \times 10^9$/L), being elderly (>65 years old), uncontrolled primary disease, pneumonia, hypotension, multiorgan dysfunction, invasive fungal infection, or being hospitalized at the time of fever [237]. The advantages, disadvantages, and indications for the use of these cytokines are discussed in more detail elsewhere (see Chapter 43).

Several other cytokines, including transforming growth factor-beta [238] and keratinocyte growth factor [239], have been shown in preclinical studies to enhance mucosal stem-cell regrowth. Clinical trials have shown that both recombinant human keratinocyte growth factor (palifermin) and repifermin are able to reduce the severity of mucositis [240,241]. Since mucositis is associated with infection [8,242], whether or not these molecules reduce the risk for infection was an important consideration. Palifermin treatment was found to be associated with a reduction in the incidence of febrile neutropenia (75% palifermin versus 92% placebo, $p < 0.001$), and a non-significant trend towards a lower rate of bacteremia [240]. Repifermin was associated with a lower rate of non-neutropenic fever; however, no difference in rates of febrile neutropenia was observed [241]. Other agents that have been evaluated for their ability to decrease mucosal toxicity and subsequent infections in cancer patients include GM-CSF mouthwash, glutamine, and low-level laser therapy. None of these agents has consistently demonstrated reductions in infection rates, antibacterial consumption, or length of stay of HCT recipients. Of note, the use of GM-CSF mouthwash in HCT recipients is discouraged in the new mucositis guidelines published by the Multinational Association of Supportive Care in Cancer.

Granulocyte transfusions

During the 1970s, granulocyte transfusions were frequently used to treat or prevent infections in severely neutropenic patients [243,244]. Unfortunately, they were found to have only marginal benefit in most individuals, perhaps in part due to the low number of granulocytes mobilized. Moreover, they often transmitted CMV from donors and morbidity frequently developed from the acquired CMV infection. Today, with modern antibiotic regimens, the need for granulocyte transfusions has diminished. However, they can be useful where bacterial infection from an organism resistant to multiple antibiotics is present or the infection progresses despite the administration of optimal antimicrobial agents [245,246]. The use of granulocyte donors who are serologically negative for CMV eliminates the risk of transmitting CMV.

The use of growth factors such as G-CSF or GM-CSF, alone or in combination with corticosteroids, to stimulate granulocyte production and mobilization into the peripheral blood has led to the potential for collecting large numbers of granulocytes from normal donors [245,247], and the use of these "enhanced" granulocyte transfusion products for the treatment of severe infection. It has yet to be demonstrated whether this approach offers significant clinical benefit. A Cochrane review in 2005 found that there is inconclusive evidence from available trials to support or reject routine use of granulocyte transfusions [246]. Since that review, several small series have been published, although only one was a randomized trial that was closed prematurely due to poor enrollment [248]. Randomized controlled trials are needed to establish definitively the role of granulocyte transfusions in the treatment of infections in patients with neutropenia or neutrophil dysfunction, and until these results are available granulocyte transfusions are not recommended for routine use. If granulocyte transfusions are prescribed, the recommended dose to be administered should be $\geq 2 \times 10^{10}$ polymorphonuclear cells/dose with corticosteroid stimulation or $\geq 4 \times 10^{10}$/dose with G-CSF continued until either the infection resolves or the WBC count is $>1 \times 10^9$/L [247].

An alternative approach is to collect G-CSF-mobilized granulocytes and administer them to patients prophylactically post-transplant, during the expected neutropenic window, to facilitate accelerated neutrophil recovery [249]. This approach has been shown to reduce the number of patients who develop fever while hospitalized, the number of febrile days, and the duration of antibacterial therapy in a small series. Additional research on the validity of such an approach is needed, and may be suitable only for patients at high risk for serious or antibiotic-resistant infections.

Immunobiologic agents

Several studies have shown that the use of IVIg reduces bacterial, fungal, and viral infections after allogeneic HCT [250–253], but others have not [254,255], including a controlled trial in autologous HCT patients [255]. The relative merits of IVIg as a general antimicrobial measure versus the specific antimicrobial agents mentioned above remain unclear. Generally, IVIg is well tolerated. Its disadvantages include its high cost, large fluid volumes, need for parenteral administration, and occasional side effects. Beyond day 90, IVIg given as a monthly infusion was of no benefit in reducing bacterial infections, and routine use is not recommended in consensus guidelines [6,251]. Moreover, there was no reduction in the incidence of bronchiolitis obliterans, overall survival, or survival from cGVHD, and serum IgG and

IgA levels in patients who received IVIg were lower than those in control subjects, suggesting that the use of IVIg might retard humoral immune recovery. Although there may be other reasons to consider the use of immune globulin (e.g. to reduce GVHD or interstitial pneumonia), its high cost and cheaper antibiotic alternatives do not make this approach attractive for the prevention of bacterial infections.

Activated protein C has been shown to be effective in the treatment of sepsis syndrome, which frequently complicates HCT and is associated with significant morbidity and mortality. This syndrome is the end result of the activation of inflammatory and coagulation cascades in response to infection [256]. Activated protein C is an endogenous protein that is important in maintaining circulatory homeostasis. In sepsis, concentrations are depleted, a factor that has been associated with poor outcomes in septic patients.

Activated protein C has several actions; those of most importance in sepsis are the anti-inflammatory, profibrinolytic, and anticoagulant activities. Drotecogin alfa, a recombinant human activated protein C, has been shown to reduce the relative and absolute risks of death in septic individuals [256,257]. In the pivotal FDA licensing trial, HCT recipients were excluded owing to increased risk from bleeding complications in an already thrombocytopenic population. Since FDA approval, some investigators have used this agent in high-risk thrombocytopenic HCT recipients, with mixed success [258]. The benefits of administration should be weighed against the potential risks of treatment.

Conclusion

The morbidity and mortality from infection have improved dramatically in recent years as insights into the deficits in host bacterial pathogenesis and epidemiology of infections, the introduction of more effective and less toxic antimicrobial regimens, and improved strategies of using various antimicrobial agents have translated into effective therapeutic approaches. Such advances have facilitated enormous strides in reducing transplant-associated mortality, thereby improving the acceptability of HCT as a treatment option for an ever-widening array of malignant and non-malignant diseases.

Variations in the epidemiology of opportunistic pathogens, the ever-continuing emergence of antimicrobial resistance among microorganisms, changes in host characteristics due to new preparative and immunosuppressive regimens, the application of HCT to new patient populations (older ages, different hematopoietic cell sources, and different underlying diseases), and the adoption of post-transplant immunoadjuvant therapies to reduce the risk for relapse in the autologous transplant setting require continuing vigilance, and will pose new challenges for the control of bacterial infections. Better diagnostic tools to detect pathogens more accurately and rapidly, and to detect them earlier in the course of infection, are needed. Newer antimicrobial agents that are safer and more effective, with a broader spectrum of activity, must be sought. The expanding array of biologic agents to modify pathogen virulence and host responses to infection offer the opportunity to reduce host susceptibility to infection, and will likely prove important adjuncts to antimicrobial agents directed against the growing repertoire of opportunistic pathogens.

CHAPTER 86

Fungal Infections After Hematopoietic Cell Transplantation

Kieren A. Marr
Johns Hopkins University School of Medicine and the Sidney Kimmel Comprehensive Cancer Center, Baltimore, MD, USA

Introduction

Invasive fungal infections (IFIs) are among the leading causes of infectious morbidity following allogeneic hematopoietic cell transplantation (HCT) in adults and children, especially since the 1990s [1,2]. The rising incidence of these infections, the emergence of "new" fungi, the refinement of new diagnostic modalities, and the introduction of the broadest array of antifungal drugs in the history of medicine have resulted in a sustained renaissance in the study of IFIs.

There are three major classes of medically important fungi: yeasts, molds, and dimorphic fungi. One genus of yeast, *Candida* spp., and one genus of mold, *Aspergillus* spp. cause more than 80% of all IFIs in HCT recipients. *Candida* spp. are distinguished by their lack of branching hyphae, existing primarily as unicellular yeast. These are prominent mucocutaneous colonizers, but can cause disease when barriers are breached. Molds, such as *Aspergillus* spp., are most commonly transmitted via inhalation of conidia (spore) forms and have true, branching hyphae. The dimorphic fungi, such as *Coccidioides immitis/posadasii* and *Histoplasma capsulatum*, can grow as both molds (in the environment), and yeasts (in the body).

Much has been learned over the last two decades regarding the epidemiology and risks for IFI, and how to prevent and treat these infections effectively. A large review comparing over 2500 patients who received allogeneic HCT in Seattle over two different periods (1993–1997 vs. 2003–2008) showed lower risks for death caused by both *Candida* species and molds in the recent cohort [3]. Strides have been made in all arenas – screening for early diagnoses, prophylaxis, and improvements in the treatment of established disease. This chapter focuses on the clinically significant infections and how to prevent and treat them. Attention is drawn to infections caused by *Aspergillus* and *Candida* spp., which are the most important in people who have received HCT. Infections caused by other fungi, including *Pneumocystis jirovecii*, the agents of mucormycosis, are discussed briefly.

Infections caused by *Candida* species

Mycology and epidemiology

Candida spp. typically reside on the skin and mucous membranes of the gastrointestinal (GI) and genital tracts. There are numerous species of *Candida*, each of which differs with regard to its biology and predilection for colonization, accounting for variability in the risks and prevalence of disease caused by each. Risks for invasive infections typically cause breakdown in initial defenses, or they increase *Candida* colonization (or both). They include mucositis, neutropenia, graft-versus-host disease (GVHD), administration of broad-spectrum antibiotics and total parenteral nutrition, and central venous catheters.

Of the numerous species of *Candida*, *C. albicans*, *C. glabrata*, *C. krusei*, *C. tropicalis*, and *C. parapsilosis* are the most common organisms associated with invasive disease [23,24]. These organisms differ in their intrinsic ability to cause infection, and also their ability to exhibit resistance to antifungal drugs. *C. albicans* is by far the most "virulent" of the *Candida* species (and the best studied), in part due to its ability to create hyphae that can invade and adhere to mucous membranes and tissues [4]. Other species, such as *C. glabrata* and *C. krusei*, also cause disease, but at lower frequency; the exception to this rule is in the setting of fluconazole prophylaxis, which selects for colonization of these more resistant organisms. The incidence and species distribution of reported disease thus depend on institutional prophylaxis practices [5]. In a recent prospective surveillance study performed in 23 transplant centers in the United States (TRANSNET), *C. glabrata* was the most common organism identified to cause IFIs, followed by *C. albicans*, *C. parapsilosis*, *C. tropicalis*, and *C. krusei* [6]. Pediatric programs often report a relatively increased incidence of infections caused by *C. parapsilosis*, which are more commonly introduced exogenously via infusates and/or skin. *C. tropicalis* causes disease more frequently in people with leukemia, for reasons that are not entirely clear [7]. The bottom line is that these species are unique, and the frequency of infection is associated with specific host and treatment characteristics in different patients.

Pathogenesis and immunity

The association between neutropenia and IFIs has long been recognized; however, recent years have brought into focus the understanding that defenses against these commensals are redundant and complicated, with overall risks being a function of both acquired defects and innate immune variability.

The high incidence of mucosal candidal infection associated with human immunodeficiency virus (HIV) infection first highlighted the clinically significant role of the CD4 T cell in anticandidal defense. Studies demonstrated that invasive candidal infection follows adhesion of the organism to the cell surfaces, which induces proinflammatory cytokine responses. Various immune effectors are involved in the response to organism invasion. Neutrophils damage

candidal pseudohyphae and phagocytose yeasts, and serve to modulate the innate immune response, largely functioning to dampen the proinflammatory response [8]. Both dendritic cells (DCs) and macrophages attach to and ingest candidal yeasts and hyphae, presenting fungal antigens to T cells [84]. Recovery from infection is dependent on CD4$^+$ T helper type 1 (T_H1) cytokine enhancement of monocyte and neutrophil function. Studies using antibodies and/or knockout mice have demonstrated that interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), and interleukin (IL)-18 are important in the defense against invasive candidiasis. The balance of cytokines and the nature of CD4 T cell responses are important in modulating risks for both mucosal and invasive disease.

There is a critical difference in the innate immune response to *Candida* yeasts versus hyphal forms, largely dictated by dectin-1 recognition of β-glucan, which is differentially expressed based on morphology [4]. Not only does this provide an explanation for mammalian ability to differentiate between potential "colonization" and "invasion," but it has also led to studies that are now explaining individual genetic risks after HCT. These suggest that a loss-of-function polymorphism in dectin-1 results in lower cytokine responses and increased *Candida* colonization of the GI tract in HCT recipients [9]. It has been postulated that increased colonization may predispose to development of GI tract GVHD, possibly through dectin-1 effects on T-cell immunity [10,11].

Clinical manifestations

Multiple clinical syndromes associated with *Candida* spp. have been described. Primary syndromes and secondary manifestations of invasive disease are discussed here.

Mucocutaneous infection

The classic mucocutaneous manifestation is thrush, which appears with white plaques in the mouth. *Candida* also causes angular cheilitis. Esophagitis and involvement of other areas of the GI tract can occur in the absence of thrush, and the associated complaints of dysphagia, substernal chest pain, nausea, vomiting, and upper GI bleeding are indistinguishable from esophagitis due to other etiologies. The stomach is the second most common GI site of candidal infection, followed by the large and small bowel. Findings at endoscopy include white plaques, single or multiple ulcers, erosions, and pseudomembrane formation. Mucocutaneous infection can lead to invasive disease, especially with concurrent damage to mucosal integrity.

Candidemia, or acute disseminated candidiasis

Following HCT, there is a higher incidence of dissemination to peripheral sites. Although the liver, spleen, and lungs are most frequently affected, virtually all other organs are at risk for seeding, including the kidneys, brain, heart (myocarditis or endocarditis), central nervous system (CNS), vascular endothelium, bone, and eye (endophthalmitis). Microabscesses are the hallmark of candidal tissue invasion. Hence disseminated disease may not be clinically apparent at the time of positive cultures.

Candida species can go to the eye and the skin as primary sites of hematogenous seeding. "Endophthalmitis" implies infection of the vitreous and/or aqueous humor, which typically occurs as chorioretinitis that can progress to produce vitreous and sometimes aqueous infection. Eye examinations should be performed on people with candidemia, as effective therapy may require surgical intervention. Skin lesions are also common, especially with infection caused by *C. albicans* and *C. tropicalis*. These are typically small, papular or pustular, and painful, and can occur in a widespread distribution, depending on the species and fungal burden (Figure 86.1).

Candida spp. are capable of attaching to the endothelium and to catheters, which may explain the presence of endovascular infections, such as endocarditis and thrombophlebitis. Thrombophlebitis is most commonly a post mortem diagnosis; however, the classic, albeit rarely seen, presentation includes a patient with localizing extremity edema and a history of protracted broad-spectrum antibiotic and/or total parenteral nutrition administration via a central venous catheter. Although rare, *Candida* spp. are the most common cause of fungal endocarditis.

Candida species can disseminate to the lungs via hematogenous spread, but these organisms rarely cause disease by airway invasion. For this reason, cultures of sputum or bronchoalveolar lavage fluid have limited diagnostic value. Computed tomography (CT) scans of the chest may show abnormalities suggestive of nodular disease. In one study, CT findings in HCT recipients with histopathologically proven pulmonary candidiasis included multiple nodules, seen in 15 of the 17 (88%) patients studied. In nearly half of the patients, the nodules were described as centrilobular with a tree-in-bud pattern, and in 75% of these scans the nodules were bilateral. A majority of

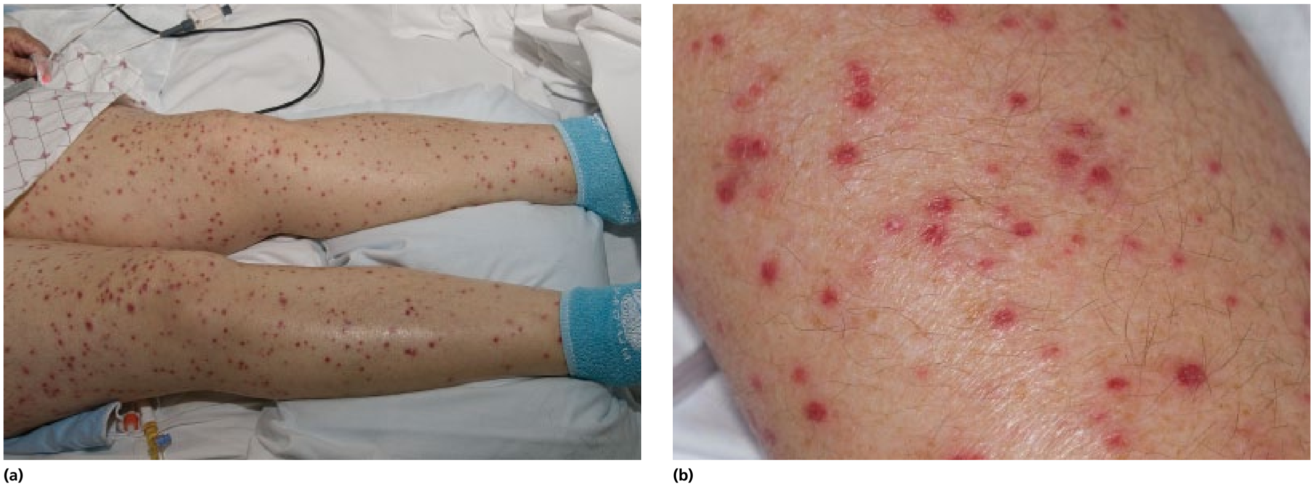

Figure 86.1 Skin lesions caused by *Candida tropicalis* in a patient who was neutropenic after therapy for AML.

patients had associated air-space consolidation, and even ground-glass opacities, pleural effusions, thickening of the bronchial walls, and cavitation [12]. Hence it is difficult to distinguish lesions caused by hematogenous dissemination of *Candida* spp. from organisms that invade through the airway (e.g. *Aspergillus* spp.).

Hepatosplenic candidiasis, or chronic disseminated candidiasis

Hepatosplenic candidiasis is probably the most common syndrome of disseminated infection, although it is infrequently diagnosed to a microbial level. The pathogenesis of hepatosplenic candidiasis is unique, as the organism is acquired through portal vasculature, in the setting of mucosal breakdown, *Candida* colonization, and neutropenia. Symptoms typically occur concurrent with progressive inflammation after neutrophil engraftment, with histopathology demonstrating more granulomatous inflammation; hence this syndrome is also referred to as "chronic disseminated candidiasis" [13]. People usually present with persistent fever, and may have abdominal pain, and elevated liver function tests, especially alkaline phosphatase. Recently, attention has focused on the potential development of an immune reconstitution syndrome in driving protracted symptomatology, as discussed in greater depth below.

Diagnosis and therapy

Diagnosis

The diagnosis of candidemia usually relies on the identification of *Candida* species from blood cultures. Blood culture sensitivity, even with new culture methodologies, is relatively poor; with this in mind, a person can have an invasive infection without having positive cultures.

Multiple non-culture-based assays have been studied for adjunctive diagnostic use, including methods to identify antigens (mannan, glucan), and also polymerase chain reaction (PCR) assays to detect nucleic acids. These assays may have utility in detecting early disease; when compared with blood cultures, a multiplex PCR designed to amplify unique sequences of *C. albicans* provided results in 8 hours and had a sensitivity of 96.9% [36]. Although PCR assays have been introduced in some reference centers, they are not widely available to most clinicians. The US Food and Drug Administration (FDA) cleared an assay that detects β-glucan for use to assist diagnosis of IFI; these assays have been more widely utilized in Japan. The FDA-cleared assay was initially evaluated in the setting of neutropenic fever, and in this setting it has approximately 80% sensitivity and specificity for diagnosis of candidemia [14,15]. In a small evaluation of HCT recipients, the assay became positive a median of 2.5 days after blood culture positivity, but the assay remained positive after cultures had cleared [16]. It is important to remember that circulating β-glucan can be present with multiple fungal infections and other states, with bacteremia and infusion of some drugs [e.g. intravenous immunoglobulin (IVIg)] triggering "false positives."

The diagnosis of hepatic candidiasis typically relies on imaging. With a reported sensitivity of over 90%, CT scans of the abdomen performed with intravenous (IV) contrast are more sensitive than ultrasound examinations. One prospective study examined the role of magnetic resonance imaging (MRI) scans in patients with suspected hepatosplenic candidiasis, revealing high positive and negative predictive values (85% and 100%, respectively, with a sensitivity of 100%). In 11 of 13 patients with hepatosplenic abnormalities, the lesions were less than 1 cm in diameter and were described as well-defined, high signal intensity foci on T1-weighted images [34].

Preventative therapy

Strategies to prevent candidiasis include (1) *primary prophylaxis*, defined as the administration of antifungal drugs in the absence of any evidence of infection, (2) *secondary prophylaxis*, defined as the administration of agents to patients with a history of prior IFIs, and (3) *empiric treatment*, defined as the administration of agents based on a defined but non-diagnostic clinical indication, but without proven IFIs. The prototypic empiric therapy is the use of antifungals in patients with fever during neutropenia. Here, primary prophylaxis is discussed only, given the complexity in interpreting the efficacy of other preventative strategies and widespread adoption of primary prophylaxis strategies in HCT recipients.

The first well-designed placebo-controlled multicenter trial that evaluated fluconazole for primary prophylaxis pre-engraftment showed that candidiasis rates were decreased within the active drug arm, although overall mortality did not differ [17]. In this study, approximately half of the subjects enrolled were recipients of allogeneic HCT and autologous HCT, hence risks and predicted mortality caused by infection were heterogeneous. A subsequent single-center study that enrolled a larger proportion of allogeneic HCT recipients showed improved survival in people who received fluconazole for a longer period (75 days) [18]. That survival benefit was sustained in long-term follow-up analysis [19]. The real benefit of long-term administration of fluconazole has been controversial, and most guidelines have suggested that fluconazole is useful primarily during the pre-engraftment period [20]. Looking back at this issue, it is interesting that the long-term follow-up analysis did observe a benefit of fluconazole associated with GI tract GVHD scores; perhaps some of the benefits could be explained by recent observations that *Candida* gut colonization exacerbates the development of GVHD in select individuals with dectin-1 polymorphisms [10,11,21]. Despite its excellent activity against most *Candida* spp., it is not useful in the treatment of infections due to select species, especially *C. glabrata* and *C. krusei*, which proportionally cause more invasive disease in people receiving fluconazole [22].

The major limitation of fluconazole is its lack of activity against molds. Hence the availability of well-tolerated, broad-spectrum agents renewed the search for a regimen to prevent these more lethal IFIs. Lipid formulations of amphotericin B, multiple broad-spectrum triazoles, and echinocandins have all been or are being studied for their utility as a prophylactic antifungal in various high-risk populations. All studies to date have confirmed our ability to prevent invasive candidiasis; however, the data regarding preventing proven mold infections and reducing fungal-related mortality are more controversial, as discussed in detail in the next section.

Treatment of invasive candidiasis

Multiple antifungal drugs have been made available and shown to be effective in treating invasive candidiasis. These drugs have different mechanisms of actions and different toxicities and drug interactions, as outlined in Figure 86.2 and Table 86.1. In general, the utility of each is specific to the patient with the infection, and the predicted (or measured) susceptibility of the causative *Candida* species.

The utility of fluconazole for the primary treatment of candidiasis is relatively limited in this population owing to extensive prior exposure that selects resistant organisms, and the lack of robust clinical trial data. Although studies have shown that fluconazole is not inferior to amphotericin B deoxycholate and echinocandins for treatment of candidiasis, these studies enrolled

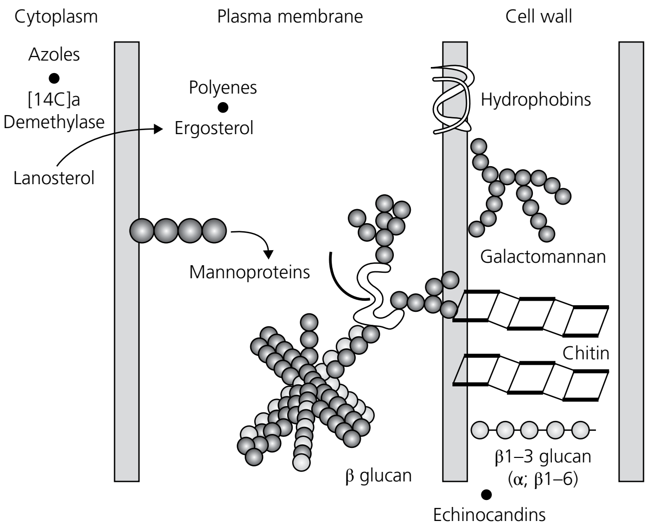

Figure 86.2 Schematic mechanisms of actions of three current classes of antifungal drugs.

Table 86.1 Systemic administered antifungal agents

Antifungal agent	Spectrum	Route	Most common toxicities	Drug interactions
Polyenes				
Amphotericin B	Yeasts and molds	IV	Infusion-related, nephrotoxicity, hypokalemia, hemolysis	Concomitant administration of other nephrotoxic agents increases risk for Ampho-induced renal failure
ABCD	Yeasts and molds	IV	Infusion-related, nephrotoxicity	Less potential for nephrotoxicity than Ampho B
ABLC	Yeasts and molds	IV	Nephrotoxicity	Less potential for nephrotoxicity than Ampho B
Liposomal amphotericin	Yeasts and molds	IV	Nephrotoxicity	Less potential for nephrotoxicity than Ampho B
Azoles				
Fluconazole	Yeasts	IV	Hepatic	Decreases fluconazole levels: rifampin Fluconazole increases levels of CSA, phenytoin, glipizide, glyburide, warfarin
		PO		
Itraconazole	Yeasts and molds	IV	Hepatic, hypokalemia, edema	Decrease itraconazole levels: increased gastric pH, rifampin, isoniazid, phenytoin, carbamazepine, cisapride
		PO capsules	GI, hypokalemia, edema (hepatic)	Itraconazole increases levels of: CSA, tacrolimus, steroids, digoxin, astemizole, cisapride, warfarin, vinca alkaloids, busulfan
		PO solution	GI, hypokalemia, edema (hepatic)	
Voriconazole	Yeasts and molds	IV	Visual disturbances, hepatic, neurologic, phototoxicity	Similar to fluconazole except that metabolism via CytP4502C19 introduces genetic variability in levels
		PO	As above	As above
Posaconazole	Yeasts and molds	PO	GI, hepatic	Similar to itraconazole
Echinocandins				
Caspofungin	Yeasts, less so molds	IV	Hepatic	Increases caspofungin levels: CSA
Micafungin	Yeasts, less so molds	IV	Hepatic	Increases levels of sirolimus, nifedipine, itraconazole
Anidulafungin	Yeasts, less so molds	IV	Hepatic, histamine-like reactions	CSA modestly increases anidulafungin levels

largely immune-competent (non-neutropenic) patients [23–25]. Treatment guidelines generated by the Infectious Diseases Society of America (IDSA) recommend primary therapy with an echinocandin when cultures are not yet identified to the species level; a switch to an active azole drug (fluconazole or voriconazole) can be considered with stabilization, given the IV requirements of echinocandins [26]. This approach, with an increased utilization of echinocandins for the treatment of candidemia, has been endorsed in multiple medical centers. Data generated by systematic reviews suggest potential benefits, with echinocandin-based primary therapy, with the exceptions noted for organisms that have relative resistance to these drugs [27].

One of the treatment questions that has arisen with the introduction of multiple antifungal drugs concerns the utility of susceptibility testing to guide therapy. Although this question is largely beyond the scope of this chapter, it is useful for all clinicians to recognize that drug choice should be tailored to the predicted susceptibility of the causative species. For instance, *C. glabrata* is a species that may become resistant to fluconazole over time, largely by expression of cellular efflux pumps [28]; use of an azole for primary therapy of severe disease should be approached cautiously. *C. krusei* is never susceptible to fluconazole, but it is sensitive to voriconazole, and also other options (echinocandins). Other species, especially *C. parapsilosis*, appear to have innately decreased susceptibility to echinocandin drugs, and studies have shown that others can become resistant to echinocandins over time, by mutation of a gene involved in the drug target [29].

Current recommendations are to continue an active antifungal agent for at least 2 weeks after clearance of blood cultures [26]. These recommendations are based on the observation that the organism may seed other sites without presenting signs of infection, and this can become clinically apparent later, if antifungal therapy is discontinued prematurely. One site that is important to evaluate is the eye; as discussed above, chorioretinitis, with or without vitreal involvement, can be common, and noting this development is important both to guide appropriate choice of antifungal drugs and for consideration of surgical therapy. Both fluconazole and voriconazole have good distribution into the eye, but echinocandin drugs do not. Vitrectomy, or injection of an antifungal into the vitreous humor, are important considerations to resolve infection, so ophthalmology should be involved in the care of these patients.

Candidemia can originate from an intravascular catheter or secondarily seed a catheter in the setting of high fungal burden. For this reason, historic recommendations have been that catheters should be removed from infected individuals. It has been noted that in the absence of either randomized or clear observational data in this subset of patients who usually acquire infection through the gut, this recommendation may not be appropriate [30]. Current recommendations are to remove the catheter, *when feasible*. This obviously is a highly individualized decision in people with hemodynamic compromise. Resolution of symptoms (primarily fever) following the removal of the central venous catheter does not obviate the need for antifungal therapy.

Treatment of hepatosplenic candidiasis follows a similar rationale as that described above, and multiple drugs have utility, including amphotericin products, azoles, and echinocandins. There are a few things to note. First, it is rare to have microbiologic confirmation to the species level, so a regimen that is broader than fluconazole is usually a good place to start. That said, *C. albicans*, the species that can most effectively invade the gut into the portal vasculature, is the most common cause of disease and fluconazole may be appropriate maintenance therapy, especially for people who have no prior exposure to azole-based prophylaxis during neutropenia. Also, one of the major therapeutic issues in treating hepatosplenic candidiasis concerns the duration of therapy, as patients typically have protracted courses of fever. Prolonged symptomatology can lead to frequent changes in antifungal regimens and increased, unnecessary toxicities, as the fever can be largely driven by inflammation rather than persistence or growth of the fungus itself. For this reason, investigators have recently questioned the utility of anti-inflammatory agents in augmenting therapy in this setting. Adjunctive corticosteroid therapy has been preliminarily evaluated for this entity, frequently referred to as an “immune reconstitution syndrome,” but definitive trials have not been performed [31,32].

Table 86.2 Host and therapeutic risks for invasive aspergillosis (IA) after allogeneic HCT

Variable	“Early” IA[a]	“Late” IA[a]
Host	Advanced age	Advanced age
	Underlying disease: other than CML	Underlying disease: MM
	CMV seropositive, disease	CMV seropositive, disease
	Prior IA	Prior IA
	Polymorphisms in innate immune genes	Polymorphisms in innate immune genes
Transplant	Bone marrow, cord blood	Peripheral blood, T-cell depletion
	Myeloablative conditioning	Non-ablative conditioning
	Donor TLR4, dectin-1 polymorphisms	Donor TLR4 polymorphism, D$^+$/R$^-$
	Hospital exposure, airway colonization	Ambient exposure, season
Complications	Poor engraftment	GVHD and therapies
		CMV, respiratory virus infections
		Secondary neutropenia, lymphopenia
		High iron stores

CML, chronic myelogenous leukemia; CMV, cytomegalovirus; D$^+$, seropositive donor; MM, multiple myeloma; R$^-$, seronegative recipient; TLR, Toll like receptor.

[a] “Early” and “Late” defined as in earlier studies, at approximately day 40 cut-off.

Infections caused by *Aspergillus* species

Mycology and epidemiology

Aspergillus spores are thermotolerant and abundant in the environment. Exposure to spores likely occurs all the time, as they are found throughout Nature, particularly associated with decaying vegetation and soil, barns, compost piles, and plants; exposure is primarily through the airway, with normal inhalation or smoking (tobacco or marijuana). *Aspergillus* species, particularly *A. niger*, can also be ingested in foods and are found in peppers and spices. Filamentous fungi, including *Aspergillus*, have also been isolated from water supplies, likely as they can grow as biofilms [33].

Most cases of invasive aspergillosis (IA) are caused by *A. fumigatus*, although other species, particularly *A. flavus* and *A. terreus*, also cause disease. The marked predominance of *A. fumigatus* may be explained in part by its ubiquity in Nature, thermotolerance, and rapid growth rate, and also multiple “virulence” characteristics, as briefly discussed below. Recently, it was recognized that *A. fumigatus* is not one species, but contains multiple different “cryptic species” [34]. Although these organisms appear very similar and are frequently identified as *A. fumigatus* based on morphologic characteristics, they are genetically unique and exhibit differences in growth features that may be clinically important. For instance, *A. lentulus* typically exhibits higher resistance profiles to different antifungal drugs. This is discussed in depth in the therapy section below; it is important here only in clarifying that based on genetic analyses, many of the previously considered single species are considered “groups,” and some are being given new names [35–37].

Historically, IA was thought to be an infection that occurred primarily in hospitalized patients during neutropenia, and focus was placed on potential sources of nosocomial transmission, in “outbreak” settings. However, in the 1990s, important epidemiologic studies outlined the observation that increasing numbers of cases were occurring in HCT patients, with a bulk of diagnoses established after engraftment, during periods of severe GVHD or with T-cell depletion [1,38]. Thus, “late” cases illustrate the complexity of host defenses to these organisms. It also emphasizes the importance of environmental, non-hospital sources of exposure. In fact, environmental exposure, which appear to be geographically variable, possibly accounts for differences in observed rates of IA. Recent studies have shown that ambient quantities of *Aspergillus* spp. (and other filamentous fungi) are variable according to season in some geographies, corresponding to weather changes (both temperature and precipitation) [39]. Suffice it to say that exposure appears to be a complex variable that differs between transplant centers, dictated by hospital sources and also environmental variables that influence the amount of filamentous fungus in the air.

An individual’s quantitative risk for IA is complex, and dictated by host and treatment variables that impact the immune response at the level of airway conidial clearance, local pulmonary immune responses, and systemic immunity. With this in mind, host genetics, pulmonary function, type of underlying diseases and prior therapy, conditioning regimens, stem-cell sources, and numerous complications, including GVHD (and treatment), and other infections [e.g. cytomegalovirus (CMV)] serve as clinical risks for IA during either early and/or late risk periods after allogeneic HCT. Some risks are detailed in Table 86.2.

Multiple studies have attempted to determine the actual observed incidence of IA in HCT recipients. While large single-center studies have typically reported relatively high incidences of pulmonary aspergillosis, some more recent multicenter studies did not support these findings. In the TRANSNET study, the measured cumulative incidence of IA following allogeneic HCT was less than 5%, and the incidence of IA following autologous HCT was less than 1% [6]. Another multicenter observational study performed in the United States (the PATH Alliance) reported similar low rates [40]. However, the latter study produced a very important observation, namely that there is a wide variability in IA reported by different centers; in that study, the bulk of cases in either allogeneic or autologous HCT recipients were reported from just two centers. This wide variability is likely the result of differences in geography and also a large amount of diagnostic bias that results from differences in the utilization of bronchoscopy to confirm diagnosis, and variable long-term follow-up case capture. It is important to note that neither of these £prospective surveillance” studies employed active surveillance or event-driven data capture. Many questions about the epidemiology of IA remain.

Pathogenesis and immunity

These organisms are typically acquired by inhalation of conidia, which are produced by sporulating molds in the environment; the small size and hydrophobic coating of these spores facilitate efficient aerosolization deep into the airway, and immune evasion [41]. The inoculum necessary to cause disease and the time of exposure relative to disease onset are largely unknown and likely different in individual people. Patients may be colonized for some time before development of disease with subsequent immunocompromise.

Conidia that escape mucociliary defenses or uptake by airway epithelial cells or local phagocytes can germinate into hyphae, which are the tissue-invasive form of the organism. Soon after tissue invasion, the hyphae are damaged and destroyed by neutrophils. A variety of different antigens are expressed during the morphologic changes between conidia and germtubes; probably the most important appears to be morphologic transitioning of β-glucan exposure. This is exposed on the cell wall after the hydrophobic coat of conidia sloughs off, resulting in effective recognition by phagocyte dectin-1 receptors, which drives differential inflammatory responses and the nature of resultant adaptive immunity [42].

Hence the presence and/or functioning of neutrophils represents only one, rather late response to *Aspergillus* species. There are numerous interactions proximal, and coordinate with polymorphonuclear neutrophil (PMN) responses, which involve effective recognition and clearance of conidia, and they dictate the quantity and nature of both local and systemic inflammatory responses and T-cell immunity. The importance of the latter in generating effective, sustained protection has been shown in both animals and humans. For example, DCs have a pivotal role in the defense against aspergillosis in mice and humans [43]. In addition to phagocytosing both conidia and hyphae, DCs migrate to the lymph nodes and spleen, influencing T-cell reactivity [44]. Multiple animal and clinical studies have consistently demonstrated that the specific nature of the resultant T-cell reactivity influences the host's ability to resist IA, with T_H1, T_H2, and T_H17 type of responses impacting both effector activity and potentially pathologic inflammatory responses.

The importance of cellular immunity has triggered multiple animal and human studies to explore not only risks, but also the potential utility of therapies focused on immune modulation in this unique population. In one study, lymphoproliferative responses to *A. fumigatus* antigens were more robust in healthy individuals and patients with aspergillosis who were felt to have a favorable response to antifungal agents than in patients with progressive infection [45]. Some unique *A. fumigatus* antigens may have utility in either vaccine strategies or cellular immunotherapy [46,47]. Adoptive transfer of pathogen-specific, non-recipient reactive lymphocyte clones resulted in sustained high-level IFN-γ, low levels of IL-10, and reduced mortality due to IFI in 35 recipients of haploidentical HCT [48]. This is an area of increasing understanding and exploration.

Genetic variability in innate immunity impacts risks in the transplant setting. For instance, polymorphic variation in donor Toll-like receptor 4 (TLR4) DNA confers high risks for IA in HLA-matched related HCT recipients; this risk is enhanced if the donor and/or the recipient are seropositive for CMV [49]. Other studies have associated risks for IA with polymorphisms in dectin-1, TLR1, TLR6, CXCL10, and IFN-γ genes [50–53]. Although functional phenotypes are not yet defined, and polymorphic variation likely influences the development of other HCT complications (e.g. GVHD), one may envision that these observations could eventually inform targeted prevention strategies.

The hallmark of *Aspergillus* disease is angioinvasive pulmonary infection that can result in hemorrhage, infarction, and development of lung necrosis. Angioinvasion can also result in hematogenous seeding. This classic description is much more common in people who have baseline neutropenia, which permits a higher pulmonary fungal burden; another entity, which is more consistent with progressive pulmonary inflammatory responses, or localized airway disease, has also been observed both in animal models and in HCT recipients. The distinction between airway aspergillosis and angioinvasive aspergillosis may be predictable based on both underlying diagnosis and leukocyte count [54]. Some investigators have suggested that there is a unique "immune reconstitution syndrome" that can develop in non-neutropenic hosts, with implications on diagnostic test performance [55]. More studies are necessary to understand the natural history of diseases in different hosts in order to inform diagnostic and therapeutic approaches.

Clinical manifestations

As the biology of *Aspergillus* would predict, the most common sites of inoculation are the airway and paranasal sinuses; however, disease can be acquired from and involve other sites exclusively, including the GI tract and the skin.

Sino-pulmonary aspergillosis

Both allergic and invasive diseases impact the sino-pulmonary tract. Invasive disease ranges over a spectrum that extends from manifestations isolated to the airways (e.g. tracheobronchitis) to lung parenchymal invasion, with potential for extrapulmonary dissemination.

Aspergillus tracheobronchitis is an entity that has been previously reported to occur in people who have large airway exposures concurrent with inappropriate local responses, such as that occurring in HIV-infected people who smoke marijuana. More recently, it has been reported in people with hematologic malignancies [56]. The radiographic pattern of tracheobronchitis is not "typical" of what clinicians have historically considered related to *Aspergillus* species; the entity is likely under-diagnosed. These patients typically present with airway reactivity, persistent cough, and tracheobronchitis, with characteristic findings on CT scan (Figure 86.3a). Sputum samples may persistently yield colonies of mold – often more than a few colonies – but negative cultures do not rule out this diagnosis. Bronchoscopy should be considered in patients with unexplained or chronic cough, especially when symptoms are refractory to antibacterial therapy. A variety of bronchoscopic and post-mortem findings have been described, including pseudomembranes, plaques, and balls of fungus. Risks for this type of airway disease have not been well defined; anecdotally, these patients are typically not neutropenic, and have conditions that predispose to poor airway conidial clearance, such as chronic lung disease, potentially with habits that predict high airway exposures (e.g. smoking). Other infections limited to the lower airways include laryngitis and tracheitis. The invasive potential for tracheobronchitis is documented by the detection of *Aspergillus* antigen in the blood prior to initial clinical presentation, and the subsequent development of parenchymal lesions [57].

The term "aspergillosis" is typically used to refer to a large number of invasive pulmonary manifestations. When extended

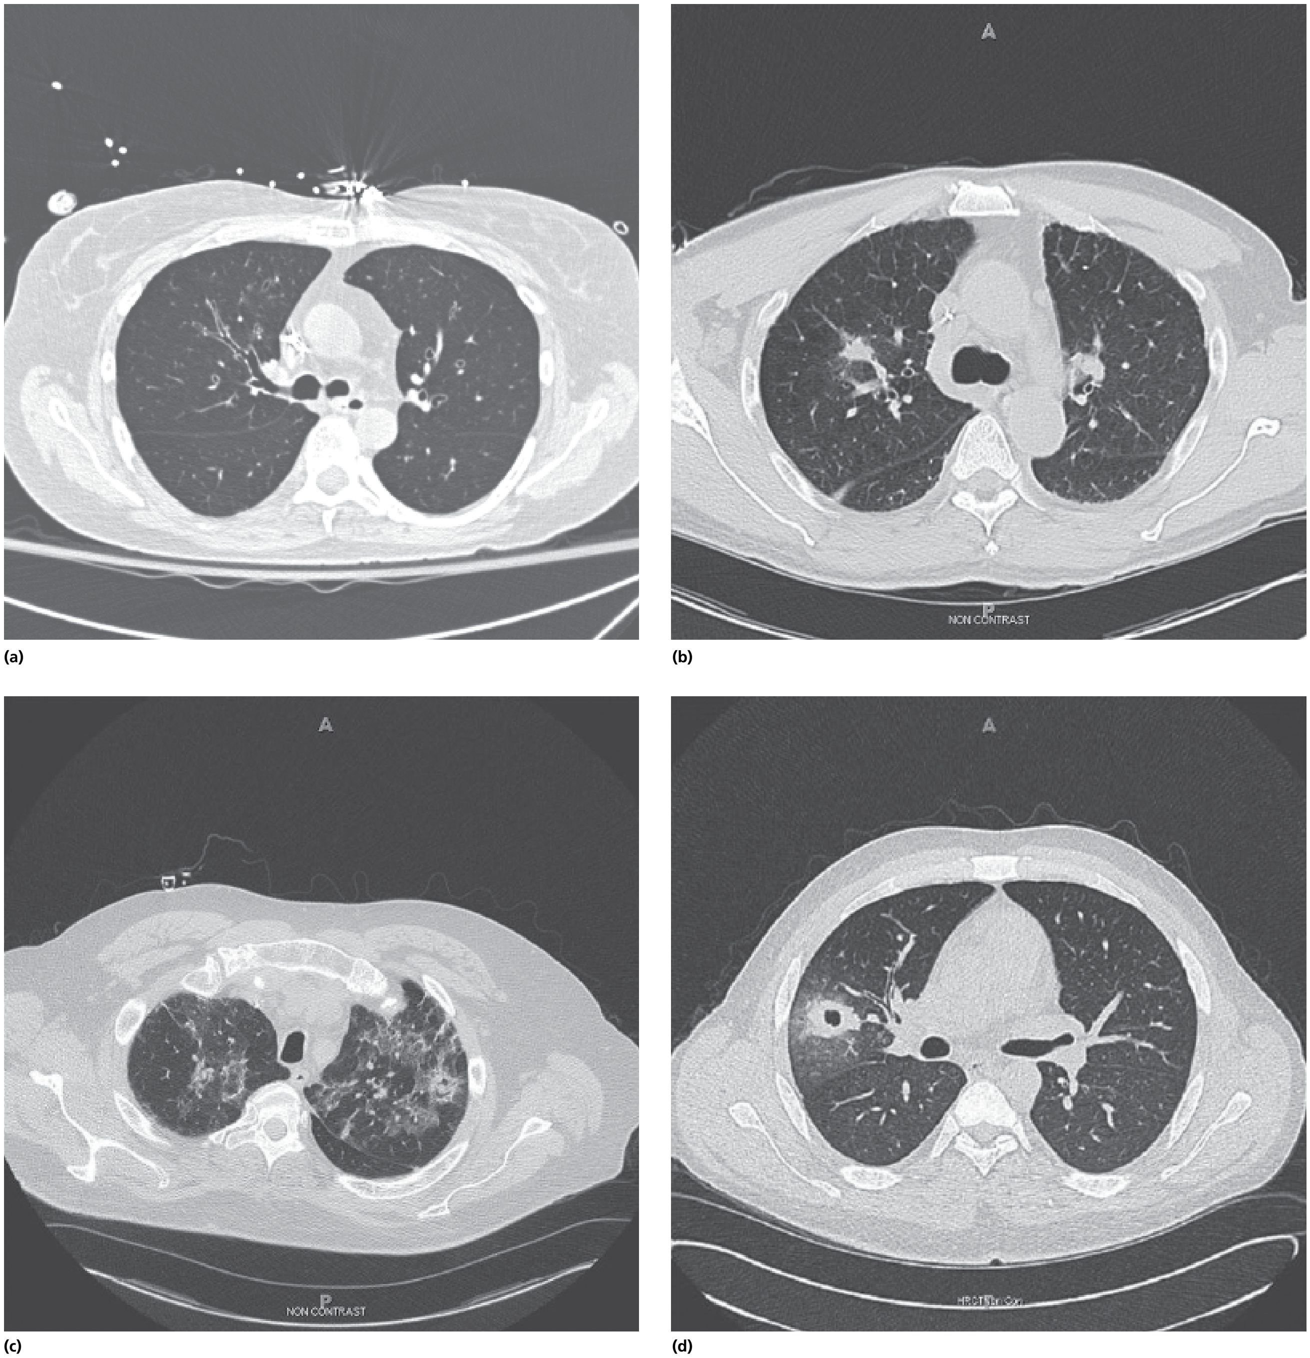

Figure 86.3 Variable radiographic appearances of documented aspergillosis in HCT recipients.(a) CT scan showing thickening and dilation of airways in an allogeneic HCT recipient with bronchoscopy-confirmed *Aspergillus* tracheobronchitis. (b) A more typical presentation of focal nodular IA. (c) Scattered nodular lesions with more ground-glass appearance and early development of a cavity. (d) A typical cavitating lesion.

beyond the airways, these organisms can be recognized to cause isolated pulmonary nodules, focal pulmonary infiltrates, or even more scattered "ground-glass" opacities (Figure 86.3b–d). Histopathologically, this disease is characterized by parenchymal hyphal invasion, which can elicit a large amount of local inflammation, hemorrhage, and eventually evolve towards necrosis. This is the genesis of radiographic findings that are frequently considered indicative of aspergillosis, with a radiographic halo produced with inflammation and hemorrhage, and cavitation developing in areas of necrosis. It is important to distinguish between an "aspergilloma" that occurs in this setting, as a result of the end-product of invasive disease, from the "aspergilloma" that can occur in a different, potentially less immunosuppressed host. In the latter, the term has been used to indicate the saprophytic overgrowth of *Aspergillus* spp. that occurs in the setting of prior lung cavities.

The presentation of IA has been historically described as most often involving fever, cough, and potentially, pleuritic chest pain. Although all of these can indicate disease, pleuritic findings appear to be more common in neutropenic patients who have some involvement of the pleura (potentially with effusion). In HCT recipients, findings may be non-specific and protean, and may not even indicate potential involvement in the lungs at all. On the other end of the spectrum are people who present with disease that has already disseminated to other organs, such as the skin or brain. As disease progresses in the lungs, it can involve adjacent structures, including the pleura, pericardium, and myocardium.

Sinusitis is usually symptomatic and not distinguishable from sinusitis due to other pathogens. Signs and symptoms suggestive of an invasive process include erosive lesions of the nasal septum, cavernous sinus thrombosis, pain with eye movement, extraocular muscle plegias, diplopia, and periorbital swelling; as this reflects late disease, with anticipated poor outcomes, a high index of suspicion is required to detect earlier fungal involvement.

Non-pulmonary aspergillosis

Aspergillus species can cause both focal infection at isolated non-pulmonary sites, and cause disease after hematogenous spread. The classic non-pulmonary site of focal infection is with cutaneous disease at sites of skin trauma, including catheter insertion. Skin lesions typically start as focal lesions, and necrosis is characteristic. If the lesion is not at a site of known trauma or there is more than one lesion, the possibility of hematogenous spread from an intravascular focus of infection including endocarditis should be considered. Dissemination from the lungs to virtually every tissue has been described, including the thyroid, kidneys, eyes, and GI tract. Classically, the worst prognosis has been observed in people who present with concurrent disease in the CNS; however, recent studies have shown that outcomes appear to be improving with voriconazole-based therapies [58].

GI involvement may result from direct invasion from the gut lumen, and can present as focal colitis. Any region of the GI tract may be involved, and a variety of findings, including diffuse infiltration, necrotizing lesions, and pseudomembrane formation, have been described. A recent retrospective study noted that a large number of patients with observed gut aspergillosis had diets that were high in spices, suggesting potential direct exposure from food products [59]. The presence of isolated GI disease should be considered in people who have persistent high galactomannan assay results in the absence of any identified pulmonary disease.

Diagnosis and therapy

Diagnosis

CT scans are important to establish an early diagnosis of IA, as they are more sensitive than chest X-ray [60]. Parenchymal lesions due to *Aspergillus* spp. may appear radiographically in multiple forms, including nodules, with or without a circumferential hemorrhage (often described as a "halo"), focal infiltrates, or lesions with necrosis (cavitation), or a combination of all of these. Radiographic findings may be highly variable following HCT, given differences in risk periods corresponding to neutropenia and/or defects in cellular immunity (Figure 86.3). In a systematic review of high-resolution CT findings in patients with pulmonary infection after HCT, the presence of large nodules and visualization of the halo sign were most suggestive of fungal infection, but these were not specific. For example, nodules that were 1 cm or more in diameter were seen in 13 (62%) of 21 patients with fungal pneumonia, but also in five (19%) of 26 patients with bacterial pneumonia, three (10%) of 30 with respiratory syncytial virus pneumonia, and three (14%) of 22 with CMV pneumonia. The halo sign was present in 10 of 21 patients with fungal pneumonia, two of 26 with bacterial pneumonia, three of 30 with respiratory syncytial virus pneumonia, and one of 22 with CMV pneumonia [61]. Also, focal infiltrates appear more common in the non-neutropenic period after HCT [62]. It has been observed that this type of "bronchopneumonic" aspergillosis may have a worse prognosis than IA compared with the classic angioinvasive presentation, although many different host-related factors also likely impact the outcomes [62].

Several studies have now documented that bronchoalveolar lavage (BAL) is both safe and assists treatment decisions. In a large review of 598 BALs performed in 501 HCT recipients at the M.D. Anderson Cancer Center, the overall yield for identification of pathogens was 55%, with a higher yield recovered from BAL performed during the first 4 days of presentation (75%). This information resulted in adjustment of antimicrobial therapy in 51% of patients, and the complication rate associated with the procedure was very low (<1%) [63]. Given the complexity of treating infectious complications in the current era of multiple drug resistance and numerous antimicrobial options, an aggressive diagnostic approach is wise.

Historical means to diagnose IA have relied on culture of the organism and identification of elements via histopathology; however, the sensitivity of culture of any respiratory sample – sputum or BAL – and the sensitivity of biopsy-based diagnosis remain very low, approximating 50% or less depending on the stage of disease. For this reason, the field has been focused on development of non-culture based methods to enhance detection of *Aspergillus* spp., using both nucleic acid and antigen detection. Numerous PCR-based tests have been developed and studied, with variable performance; some are in use on blood and/or tissues (including BAL) in different institutions.

A major advance in diagnosis has also been witnessed with more global adoption of antigen-detection strategies, especially those that detect galactomannans (GMs). GMs are cell wall components of multiple fungi, and the basis of numerous diagnostic tests, including those for IA (discussed here), and other infections (e.g. histoplasmosis). The current assay that is available in most countries is one that utilizes a rat monoclonal antibody in a double-sandwich enzyme-linked immunosorbent assay (ELISA) to detect *Aspergillus* GM. It has been studied extensively in patients with hematologic malignancies and in HCT recipients, and cleared by the FDA for use on blood and in BAL fluid. An advance in the performance of the assay was established when the cut-off to define positivity was lowered in order to achieve better sensitivity, with little compromise in specificity. A meta-analysis of 27 studies estimated that the sensitivity and specificity of the assay utilized on serum approximate 71% and 89%, respectively [64], although sensitivity is lower in people who are receiving mold-active antifungal therapy [65]. Testing for the presence of GM in BAL fluid is also very useful, particularly in people who have a high pretest probability of IA (the HCT population); studies estimated that there is a gain in sensitivity over culture alone [66,67]. This assay detects GM that is present from *Aspergillus* or related filamentous organisms, but there is some cross-reactivity caused by GM (or GM-like molecules) of other fungi. Also, false-positive assays can occur with concurrent infusion of "contaminated" infusates; several years ago, this appeared to be a particular problem with batches of piperacillin–tazobactam that were used worldwide, although this issue appears to be relatively resolved [68,69]. Higher levels of false positives in pediatric patients were historically reported, but more recent prospective studies demonstrated similar performance to that reported in adults [70]. Although not perfect, testing for GM in serum and/or BAL of people with suspected IA provides a useful adjunct to culture, and it should be performed. Results neither rule in nor rule out invasive disease, but both positive and negative test findings are informative.

Other investigators have suggested that GM and/or PCR assays can be used as screening assays to detect fungal components prior to the development of clinical signs and symptoms of disease. This approach, frequently termed "preemptive therapy," has been reported to result in earlier diagnoses, and more targeted use of antifungal drugs, and it is used in some centers, particularly in Europe [71]. Large randomized trials have not been completed to analyze clinical performance as yet, but some are under way. Preliminary results of a trial recently completed in Australia suggest that a combined screening with PCR and GM enzyme immunoassay can result in use of less antifungal drugs [72]. Optimization of these types of screening strategies is probably necessary before more widespread adoption in HCT centers.

Preventative therapy

Central to the prevention of aspergillosis is the avoidance of inhalation of spores. Given published associations, avoidance of contact with soil and plants, smoking, gardening, and maintenance of compost piles is prudent, but not demonstrated to have an impact on the rate of disease. The efficacy of wearing high-efficiency particulate air (HEPA)-filtered air masks has also not been proven in controlled studies but is a reasonable consideration. Behavioral modifications that result from wearing the mask may theoretically decrease the transmission of other infections such as those due to respiratory viruses, especially as an outpatient. Unfortunately, a small randomized trial failed to show that masks had utility [73]. In the inpatient setting, laminar airflow rooms and HEPA-filtered air may be beneficial. Although it is noteworthy that *Aspergillus* has been isolated from water, it is not clear whether avoidance of showers results in clear benefit. Evidence and guidelines for preventing infections have been reviewed by the American Society for Blood and Marrow Transplantation (ASBMT) [74].

Prophylaxis studies have been performed to evaluate multiple mold-active azole drugs (itraconazole, posaconazole, and voriconazole). The most promising results have been with the newer azole formulations posaconazole and voriconazole, which decrease the risk for invasive aspergillosis compared with fluconazole [75–77]. However, none of these studies showed improved survival, creating controversy over the utility of administration. Results of these studies are discussed in more detail here. While treatment of fever during neutropenia, or "empiric antifungal therapy," may also be considered preventive therapy for unrecognized IA, these studies are not discussed, given the complexity in interpretation of fever responses and outcomes. Readers are referred to reviews for more in-depth discussion of preventive therapies [20,78].

Itraconazole was the first mold-active azole that was studied and adopted as a prophylactic agent in this setting. Two randomized trials in allogeneic HCT recipients were performed in the United States after both the oral solution and IV forms of the drug became available. Both studies demonstrated that itraconazole administration lowered the probability of IA compared with fluconazole; however, both studies noted trends to more toxicities and lower survival in the itraconazole arm [79,80]. In one study, concurrent administration of itraconazole during cyclophosphamide-based conditioning therapy resulted in more toxicities compared with that which occurred in people who received concurrent fluconazole [80]. Detailed evaluation of metabolites suggests that this is actually the result of a relative "protective" effect of fluconazole, which selectively inhibits the P450 isoenzyme that is involved in hydroxylation of cyclophosphamide [81]. Collectively, the results of these studies suggested that prevention of IA is possible, but itraconazole is not optimal given the toxicities.

Subsequent studies evaluated the utility of the next-generation azole drugs, posaconazole and voriconazole. In a multicenter randomized trial, posaconazole decreased the incidence of IA compared with fluconazole, when administered at onset of GVHD [76]. Limitations on the use of this drug come from issues with absorption of the current formulation, which requires a slowed transit time in the small intestine, with low levels resulting in patients with severe gut GVHD [82]. A new formulation has been evaluated in phase II–III studies, with results suggesting better levels. Another multicenter study was performed in the United States, to evaluate voriconazole compared with fluconazole. This study, performed by a US consortium of bone marrow transplantation (BMT) centers (the BMT Clinical Trials Network), had a different design, with initiation of drugs pre-engraftment, and adoption of a different primary end-point, fungal-free survival (survival without an IFI) [79]. Although this study failed to show superiority of voriconazole when considering 6-month post-HCT fungal-free survival, evaluation of infection end-points again favored the mold-active drug compared with fluconazole, with a lower incidence of IA. Currently, many large centers still use fluconazole during the pre-engraftment period and then transition to either voriconazole or posaconazole with treatment of GVHD.

Other studies have been performed to evaluate echinocandins (micafungin) and lipid–amphotericin B formulations, using different routes and dosing. However, none of these studies was adequately powered to say anything definitive with regard to utility in preventing IA. The azole drugs appear to provide the most compelling potential for primary prophylaxis, given robust data and efficacy and relatively predictable toxicities, although many issues have been raised. For instance, long-term administration of voriconazole has been associated with phototoxicity that can masquerade as GVHD [83], and has been associated with skin cancers. Breakthrough fungal infections occur during administration of all azoles, sometimes associated with innate microbial resistance (e.g. zygomycetes resistance to voriconazole), and acquired resistance [84]. For instance, select institutions have reported variable but high rates of *Aspergillus* isolates that demonstrate relative resistance to azole drugs, with mutation in the target enzyme [85]. Transplant clinicians should recognize the potential for breakthrough infection associated with both microbial resistance and "failure" of effective drug delivery in chronically immunosuppressed people.

Therapy of invasive aspergillosis

Amphotericin B formulations comprised essentially the only treatment options for IA until the performance of a large randomized trial that demonstrated superiority of voriconazole compared with amphotericin B deoxycholate [86]. This study, which enrolled patients over a decade ago, showed that the 12-week survival rate after receiving voriconazole was better than after initiation of conventional amphotericin B; as predicted, a large number of patients in the conventional amphotericin arm developed infusion-related and nephrotoxicities that initiated a switch to a more tolerable formulation. One of the most notable observations was that 24% of patients with CNS aspergillosis survived – a proportion that is significantly better than what was historically observed [86]. This trend to improved survival with CNS disease has been upheld in subsequent observational studies [86].

Two large randomized trials were performed subsequently to address treatment of IA. One compared a low dose (3 mg/kg/day) of liposomal amphotericin B with a higher dose (10 mg/kg/day) [87]. The results did not show any difference in either clinical responses or survival, not supporting the high-dose regimen. At this point, the study that would be of most interest is a comparison of an azole-based (voriconazole) regimen with the liposomal amphotericin formulation. However, such a study has not been performed, so there is remaining controversy over comparative efficacy using either primary treatment option. A consensus panel convened by the IDSA suggested that voriconazole is the primary therapy of choice – at least when the diagnosis of disease due to *Aspergillus* species is confirmed [78].

The second large randomized trial performed to evaluate treatment of IA was a recently completed randomized, placebo-controlled trial that evaluated voriconazole monotherapy in comparison with the combination of voriconazole with anidulafungin, an echinocandin. Performance was supported by in vitro data, animal models, and case series that suggested potentially improved outcomes using the combination of drugs. Results have been presented in abstract form [88]. The study was different from earlier trials in that it only enrolled patients with hematological malignancies and/or HCT, and evaluated a primary end-point of 6-week survival, rather than the composite variable previously utilized to define success. The modified intent-to-treat (mITT) population included 277 patients with a diagnosis of proven or probable IA. Most patients (218/277, 78.7%) had probable IA based on positive GM antigen with concurrent radiographic findings. In the mITT, all-cause mortality at 6 weeks was 26/135 (19.3%) for combination and 39/142 (27.5%) for monotherapy [$p = 0.09$, 95% confidence interval (CI) -19.0 to 1.5]. In patients with probable IA based on GM antigen, mortality at 6 weeks was 17/108 (15.7%) for combination and 30/110 (27.3%) for monotherapy ($p < 0.05$, 95% CI -22.7 to –0.4). Safety parameters showed no significant differences between treatment groups. Based on these data, the relative enthusiasm for combination therapy has increased; however, interpretation of the results of this study, in defining whether primary combination therapy is of benefit to everyone, is a matter of active debate.

Multiple issues need to be discussed with regard to the use of voriconazole. First, dosing of the drug is a primary issue; the oral dose of 200 mg twice daily, appears insufficient for a large proportion of patients. Many have gone to weight-based dosing of both the IV and the oral formulation, and there is likely to be a role for therapeutic monitoring of drug levels to guide therapy [89]. Recently, the focus has been on other toxicities of the drug, especially the tendency towards photosensitivity and development of skin cancers. A variety of neurologic disturbances have been described, including altered or enhanced visual perception, blurred vision, changes in color vision, and photophobia. They may persist throughout the course of therapy; however, no long-term visual sequelae have been noted in animals or in clinical trials. Two randomized trials comparing other agents, posaconazole and isavuconazole, are in various stages of enrollment.

Utility of azole drugs as primary therapy for IA appears to be threatened in some geographic locations by observations of increased issues with microbial resistance. As mentioned previously, several members within the *Aspergillus fumigatus* group of organisms (e.g. *A. lentulus*) demonstrate relatively high in vitro susceptibilities to multiple drugs, and *A. fumigatus* itself has been shown to acquire mutations that confer relative resistance. The latter observation has been particularly frequent in geographic locales in which large amounts of azoles are used in agricultural practices, such as in The Netherlands, potentially explaining the variability in the phenomenon [85]. Other species, such as *A. ustus*, demonstrate variable and low susceptibility to both azoles and amphotericin B, and *A. terreus* appears relatively resistant to amphotericin specifically, with better outcomes observed with voriconazole. While there is much to learn, one needs to emphasize the relative importance of establishing a microbiologic diagnosis to guide treatment decisions.

Other issues that arise when considering treatment of IA include the utility of immune modulating therapy and the need for surgical resection of lesions. A number of in vitro studies have confirmed the salutatory effect of macrophage colony-stimulating factor (M-CSF), granulocyte colony-stimulating factor (G-CSF), and granulocyte–macrophage colony-stimulating factor (GM-CSF) on cellular response to fungus and the shortening of the neutropenic period following chemotherapy and transplantation of stem cells. GM-CSF has been shown to enhance the killing of *Aspergillus* hyphae and *Candida* spp., and also to prevent the suppression of neutrophil killing of *A. fumigatus* hyphae resulting from steroid administration [90]. Despite these findings, there has yet to be a definitive study documenting the reduction in incidence of or mortality due to IFIs. Changes in the graft composition have shortened the time to neutrophil engraftment, which has resulted in a significant reduction in the incidence of IFIs during the early post-transplant period. Other studies have evaluated the potential safety and efficacy of granulocyte transfusions, with small case series resulting in equivocal data [91,92]. Numerous other approaches are under investigation, including the use of "educated" T cells, pulsed DCs, and vaccines, but none has led to widespread clinical use to date.

The role of surgery as an adjunct for treatment of pulmonary IA is somewhat controversial. Small series have been published describing survival following both open and thoracoscopic approaches in the excision following HCT, even in the setting of GVHD, but success is not universal. Caution is necessary when lesions are adjacent to the pleura, as complicated empyemas can result from surgical disruption. Current recommendations are to consider resection in patients who are deemed acceptable surgical candidates with predominant, large lesions that are abutting vascular structures or are presenting complications with airway management, such as in the setting of contiguous necrosis with the airway or with hemorrhage. Surgical debridement is almost invariably necessary for the successful treatment of fungal sinusitis, especially with involvement with local structures.

Less common fungi

Pneumocystis jirovecii

Pneumocystis is another fungus that has attracted recent attention. Although this organism was once considered a protozoan, it was reclassified as a fungus based on genetic analyses. *Pneumocystis* causes disease only in mammals, and is species specific; whereas historical convention was to call the form *P. carinii*, the species that causes disease in humans is now appreciated to be *P. jirovecii* [93]. The natural history of disease is also becoming increasingly revealed. Most people appear to become exposed (and infected) with *P. jirovecii* early in life, and the organism can exist in the host as an airway "colonizer" for a long time. Disease may be due to either reactivation or de novo exposure, and genetic analyses of isolates recovered during outbreaks of disease in immunosuppressed hosts suggest the potential of human-to-human transmission [93].

Disease is usually limited to the lungs, although dissemination has been noted in multiple immunosuppressed hosts. The clinical manifestations have been best described in people with HIV infection; comparatively, people who have been transplanted (or are immune suppressed for reasons other than HIV) have relatively more heterogeneous manifestations, with focal in addition to diffuse disease recognized. Fungal burden in the lungs can be lower than in HIV-infected hosts, reducing the yield of diagnostic tests. An important contrast in this population is that the yields of antigen-based assays on BAL are lower than in the HIV-infected cohorts initially studied; recently, studies have suggested that serum 1,3-β-D-glucan assays have good diagnostic accuracy for *Pneumocystis* pneumonia (PCP) in many different types of immunosuppressed patients [94]. Effective prevention strategies are available, and the most effective option is trimethoprim–sulfamethoxazole (TM–SLF), which can prevent PCP with daily administration, or even staggered administration two or three times weekly [95,96]. Alternatives to TM–SLF include atovaquone, dapsone, and aerosolized pentamidine, although both pentamidine and dapsone are less effective than TM–SLF, and toxicities associated with dapsone (e.g. methemoglobulinemia and anemia) are significant [97,98]. Overall, TM–SLF is the mainstay for prevention, although *P. jirovecii* isolates with resistance to the drug due to mutations in the target enzyme gene dihydropteroate synthase have been appreciated as a cause of disease in different populations studied [99,100]. Finally, it is also important to emphasize the other "secondary" benefits associated with TM–SLF prophylaxis, as this drug may effectively prevent toxoplasmosis, pulmonary *Nocardia* infections, and infection with other susceptible organisms, such as pneumococcus [101–103]. Readers are referred to reviews for more detailed discussions on the pathogenesis, diagnosis, and treatment of PCP [96,104].

Other fungal infections

Reports of serious invasive infections caused by less commonly encountered fungi continue with apparently increasing frequency. These fungi are often referred to collectively as "emerging fungal infections," and the most commonly reported non-*Aspergillus* molds include Zygomycetes, *Fusarium* spp., and *Scedosporium* spp. [66–68]. Little is known about the epidemiology and treatment of infections due to these fungi following HCT. As these fungi often exhibit intrinsic resistance to many antifungal agents, this trend underscores the need for a detailed history of prior antifungal therapy, definitive identification of the pathogen, and appropriate use of antifungal susceptibility testing.

Zygomycetes, also referred to as the "agents of mucormycosis," are filamentous fungi that have attracted increasing attention because several epidemiologic studies performed in the early 2000s reported that they are being diagnosed at greater frequency as a cause of pulmonary disease [2,105,106]. Of particular concern was the observation that these organisms can cause "breakthrough" infection in people receiving voriconazole, either for prophylaxis or for treatment of invasive aspergillosis [107,108]. Disease and risks have been compared with aspergillosis in case–control studies; important findings include the observations that these organisms are more common in people with underlying diabetes, malnutrition, and prior voriconazole exposure [109]. These infections tend to occur later in allogeneic HCT recipients, in large part associated with complications of GVHD [6,40]. As infection can cause disease in both the sinuses and lungs, concurrent involvement should elicit suspicion for these organisms and direct antifungal therapy with an active agent [109]. As these organisms are particularly common in food and other ingested products (such as herbal medicines), disease localized to the GI tract has been reported fairly frequently. Diagnosis currently requires culture and/or histopathology, as there are no adjunctive diagnostic assays that are able to detect antigens in these organisms reliably (the GM and glucan assays do not detect these organisms). Therapy necessitates an amphotericin formulation, although some azoles, particularly posaconazole, have in vitro activity and have resulted in cure. Also, aggressive surgical debridement is a mainstay of successful therapy of invasive mucormycosis, as these organisms persist well in necrosis, are difficult to kill with antifungals, and cause a good deal of locally invasive disease. Readers are referred to reviews for further discussions of epidemiology, diagnosis, and therapy [110–112].

Fusarium species are the most common mold to be cultured from the blood, and hematogenous spread may be manifested by a stuttering appearance of skin lesions which are frequently erythematous and tender. As this organism can form "adventitial forms," or effectively sporulate, in vivo, disseminated disease is common [113]. Intrinsic resistance to multiple antifungal agents is notable, although successful treatment has been described most frequently with the use of combinations of drugs (e.g. voriconazole with liposomal amphotericin B). Several reviews on epidemiology, diagnosis, and therapy have been published [114].

Infections with *Scedosporium* spp. (*S. apiospermum* and *S. prolificans*) may mimic aspergillosis in their predilection for sinopulmonary disease; however, clues to these organisms include a higher risk of embolic skin lesions, ophthalmologic infections, and CNS disease. Like *Fusarium* species, infection is typically associated with higher fungal burdens and disseminated disease. These infections appear particularly common in certain parts of the world, such as Spain and the southeastern United States; it is likely that they are inherently "endemic" to certain regions based on environmental growth conditions. Outcomes are particularly poor with *S. prolificans*, which exhibits considerable resistance to all antifungal options. Given a substantial frequency of resistance, multiple antifungal drugs are usually recommended. Readers are referred to reviews for further discussions of epidemiology, diagnosis, and therapy [115,116].

There are many other fungi that cause disease, including multiple notable organisms distributed worldwide (*Cryptococcus neoformans*), and others that are distributed with classic "endemic" distributions in parts of North America and other regions (e.g. *Histoplasma* spp., *Coccidioides* spp., *Cryptococcus gattii*). However, for the most part, these infections are rare in HCT recipients, owing either to the type or duration of immune suppression or to the use of azole-based prophylaxis. However, it is useful to consider them among differential diagnoses, especially in endemic regions; disease can be associated with either latency with reactivation, or de novo exposure, complicating disease patterns and epidemiology.

Conclusion

Fungal pathogens are numerous and distributed worldwide, causing disease in both immune-competent and immune-suppressed people and animals. The relative "emergence" of these organisms occurred coincident with the increasing use of medical transplantation (both organ and stem cells) and the appearance of HIV infection, pointing to the relative importance of these organisms as "opportunists." Much has been learned about the epidemiology of disease in HCT recipients, especially those with longer-term cellular immunosuppression associated with GVHD; although historical reports focused almost exclusively on the role of neutrophils in combating infection, our understanding of acquired immunity and innate defenses now outlines a much more complex picture of effective host defenses and the clinical risks that lead to invasive disease. Fortunately, there have been numerous advances in diagnostics and therapies, with recent outcomes studies observing improved transplant outcomes associated with more effective preventative approaches and treatments of documented invasive disease. The expanding array of antifungal agents with differential activities and toxicities underscores the importance of diagnostics and opens up the potential for future advances. Most importantly, this chapter highlights that this field continues to be dynamic, expanding, and ever more complex, with new basic and clinical insights reported with relative frequency.

CHAPTER 87

Cytomegalovirus Infection

John A. Zaia
Center for Gene Therapy, Department of Hematology and HCT, City of Hope Medical Center, Duarte, CA, USA

Introduction

Human cytomegalovirus (CMV) has been a problem that has limited the success of hematopoietic cell transplantation (HCT) since the earliest days of the procedure [1], but, with the development of antiviral agents and improved immunosuppressive agents, CMV infection can be controlled in most patients [2]. This chapter describes the clinical aspects of CMV infection and the methods and rationale for the prevention of morbidity due to this virus. The 30-plus years of clinical studies that have led to our current methods have been reviewed in earlier editions of this book. This chapter focuses on the practical aspects of prevention and management of this infection that are important for the student, the transplant physician, and others interested in medical care of the HCT patient.

Clinical aspects of CMV infection

Viral latency

CMV is known taxonomically as human herpesvirus 5 and classified as a beta herpesvirus. CMV is a DNA virus with typical herpes virion structure (see Figure 87.1) with a genome that encodes nearly 200 proteins [3]. CMV infection establishes a latency in cells primarily of the myeloid lineage that accounts for life-long infection. The complexity of its molecular biology and functional genomics is beyond the scope of this chapter, and the reader is referred elsewhere for in-depth reviews [4].

CMV epidemiology

The epidemiological description of CMV infection in the HCT population is well described and has established that CMV infection can originate from both endogenous and exogenous sources. As shown in Table 87.1, the laboratory documentation of infection involves the detection of CMV in blood by culture ("viremia"), by detection of CMVp65 in leukocytes ("antigenemia"), by DNA polymerase chain reaction (PCR) assay ("DNAemia"), or by RNA PCR assay ("RNAemia"). Prior CMV infection in either the donor or the recipient creates the major risk factor for CMV infection in the HCT recipient, and with curtailment of blood-borne CMV exposure by the use of filtered blood products, there is virtually no CMV infection in the CMV seronegative recipient (R^-) of a seronegative donor (D^-) product. The incidence of CMV infection in allogeneic D^-R^- HCT first dropped from ~20% to nearly 0% with the introduction of CMV seronegative blood support, and currently, with filtration, it is not necessary to use selected CMV seronegative blood products for the HCT recipient [5].

In CMV seropositive recipients of either autologous or syngeneic HCT, the CMV infection rate can reach levels of up to 45%, yet CMV disease rarely occurs in these patients [6,7]. In the CMV seropositive allogeneic recipient, either D^+R^+ or D^-R^+, the incidence of CMV infection ranges from 20 to 75%, and it is in this population that the risk for CMV-associated disease occurs. The incidence of all CMV infection diagnosed at City of Hope over the past decade provides a view of CMV incidence by HCT recipient type (see Table 87.2). The lowest incidence is in autologous HCT with increasing incidence in matched related donor HCT and unrelated matched donor HCT, and highest in cord blood donor HCT. Although variation in CMV incidence is institution specific, this hierarchy of infection risk with increasing potential for HLA mismatch is the general rule.

The pathogenesis of CMV disease in the setting of HCT involves two main factors, reactivation of CMV infection and failure to control this infection, and the events that alter either of these will influence the rate of disease. The reactivation of CMV is a constant factor in autologous, syngeneic, and allogeneic HCT, suggesting that the regeneration of the marrow and reconstitution of blood elements create a milieu for CMV reactivation from a less-active state of virus dormancy, called "latency." CMV does not integrate into infected cells, but does become latent in non-dividing cells. Reconstitution of the blood elements post-HCT appears to provide the stimulation for replication of this DNA virus. Other conditioning regimen-specific factors that activate DNA repair, such as total body irradiation (TBI), could play a role in inducing CMV reactivation. However, the main element in disease pathogenesis is the initiation of control of infection, and this requires both innate and acquired immune cellular functions. Undoubtedly, variations in reconstitution of CMV immunity explain the differences in CMV disease rates among the HCT groups. As discussed later (see Cellular immunity to CMV), risk of CMV reactivation is linked to natural killer (NK) cell function and to CMV-specific T-cell immunity. With regard to T-cell reconstitution after HCT, both a homeostatic expansion of adoptively transferred T cells from the graft and T-cell production from progenitor stem cells are important. T cells transferred from the donor can provide protection from CMV [8]. However, the function of any adoptively transferred T cells is affected by inherent iatrogenic immunosuppressive treatments used in the allogeneic HCT method, such as T-cell depletion for prevention of graft-versus-host disease (GVHD) in mismatched or haploidentical HCT and corticosteroid therapy of

Table 87.1 CMV infection in blood

Event	Definition	Median days to first positive assay post-allo-HCT (range)	Median days until clearance of virus on antiviral therapy (range)
Viremia	Tissue – isolation of CMV from blood [89]	51 (37–93) [90]	0 (0–7) [90]
Antigenemia	Detection of CMV pp65 in blood leukocytes [90]	45 (27–75) [15]	13 (7–41) [90]
DNAemia	Detection of CMV DNA in plasma, whole blood, or leukocytes [15]	32 (18–46) [15,90]	12 (7–41) [90]
RNAemia	Detection of CMV RNA in plasma, whole blood, or leukocytes [24]	21 (4–82) [24]	19 (2–32) [24]

Table 87.2 Incidence of CMV infection in HCT at City of Hope[a]

Year	Incidence % (*n*)			
	Auto	MRD	URD	UCB
2004	0.0 (203)	25.7 (101)	37.3 (67)	27.3 (11)
2005	0.4 (245)	13.4 (97)	34.6 (78)	29.4 (17)
2006	0.7 (300)	12.8 (109)	28.1 (89)	42.9 (7)
2007	0.4 (264)	16.8 (113)	28.0 (118)	50.0 (12)
2008	0.4 (270)	14.5 (110)	19.2 (125)	31.6 (19)
2009	1.5 (264)	20.1 (134)	26.9 (167)	38.5 (13)
2010	1.6 (246)	20.3 (123)	28.6 (126)	69.2 (13)
2011	0.0 (254)	14.3 (105)	22.4 (134)	45.5 (11)
2012	0.3 (294)	15.6 (135)	26.6 (139)	50.0 (18)
2013[b]	0.4 (251)	11.2 (116)	25.2 (115)	59.1 (22)

Auto, autologous HCT; MRD, matched related donor HCT; URD, unrelated donor HCT; UCB, umbilical cord blood donor HCT.

[a] Percentage of HCT recipients with CMV infection in blood as determined by shell vial culture or DNA PCR in monitored blood specimens post-HCT or in tissue as determined by histopathology, n = number of HCT recipients.

[b] Data for January–October 2013.

active GVHD. Thus, T-cell depletion produces a significant risk for CMV disease, and corticosteroid therapy for GVHD significantly influences disease [2]. Even subtle effects on T-cell function can influence CMV infection and diseases, as seen with the lower infection and disease rates in HCT recipients of bone marrow versus peripheral blood-derived stem-cell products, a phenomenon thought to be due to a differential but transient delay in CMV-specific immune reconstitution [9]. Even among autologous HCT recipients, there is more risk for CMV disease if graft manipulation results in T-cell depletion. This role of T-cell protection is best demonstrated in umbilical cord blood (UCB) HCT in which only naïve T cells are transferred in the graft and immune reconstitution must rely solely on the emergence of T cells that undergo receptor rearrangement by thymopoiesis [10]. In UCB recipients, there is delayed clearance of CMV viremia until reconstitution of thymopoiesis occurs, as shown by the presence of T-cell receptor excision circles, Thus, the risk of CMV disease after HCT is a function primarily of protective cellular immunity and, as this varies with HCT method, the epidemiology of CMV disease will vary.

Historically, CMV disease presented either as pneumonitis or gastroenteritis during the 2–3 months post-HCT. With the use of preemptive antiviral treatment strategies, the natural history of CMV disease was changed to an occurrence later in the first 6 months after HCT [11]. The nature of the CMV infection can be primary or secondary, with primary infection seen mostly in the D^+R^- setting, since infection can be prevented in the D^-R^- patient treated with filtered blood products. CMV infection occurs after HCT when donor, recipient, or both have prior CMV infection (termed D^-R^+, D^+R^-, or D^+R^+), and such infections result from reactivation of CMV from latency. CMV can be typed by molecular techniques, and in reactivation infection, the CMV strain would be the same as in the primary infection. However, it is possible that reinfection could occur with a new strain of CMV, and in this situation, the virus would likely be from the seropositive donor. If CMV infection occurs after cessation of antiviral treatment, this is termed "recurrent" CMV infection.

Prevention of CMV infection after HCT

From a practical standpoint, the central risks that define how an HCT recipient should be managed are those that have predictive value for development of complicated CMV infection in the setting of inadequate immune function. When considered in this way, the important risk factors for the development of severe CMV disease are patient age, pre-transplantation CMV antibody seropositivity of donor or recipient, recipient–donor HLA-mismatch status, occurrence of acute GVHD, and delayed recovery of immunologic function post-HCT [2,5].

There are two general approaches to the prevention of CMV disease using either ganciclovir or foscarnet: (1) treatment after early detection of blood-borne CMV infection prior to onset of disease, and (2) treatment of all at-risk patients for the defined period of risk. The first approach is a "preemptive" strategy and was first shown to be effective in the HCT setting where the period of risk is well defined [12,13]. With this method, the requirement for accurate detection of CMV infection is the limiting feature, but the benefit is that fewer patients are exposed to potentially toxic antiviral chemotherapy. The second approach, termed "general prophylaxis," is used when selected patients are at particularly high risk for CMV infection, such as recipients of

UCB HCT, and all such patients are treated with an antiviral agent for the period of risk. For both strategies, the risk of CMV disease and the available virology support capabilities govern the management. There is no recommended use of intravenous immune globulin for CMV prevention in the HCT recipient [5].

Preemptive treatment strategy for prevention of CMV after HCT

Patients should be monitored for CMV infection using a test of CMV DNAemia, although other methods for determining the presence of CMV by antigenemia or RNAemia can be used [5,14]. Viremia is too insensitive and is no longer used for triggering preemptive treatment. Surveillance is started based on medical history, such that patients with a history of CMV infection in the past 6 months should be monitored prior to the conditioning therapy and all others should begin at approximately 10 days post-HCT and continued to approximately day 100. Documented CMV blood infection is treated starting with either ganciclovir, valganciclovir, or foscarnet (*note:* foscarnet is not approved in the United States for this use). Because of the variation is sensitivity of the CMV assays, there is no recommended CMV level that can uniformly trigger preemptive treatment [2]. Local institutional guidance for levels of DNAemia can be established, since it has been shown that risk groups can be defined and treatment can vary based on the level of DNAemia [15]. For example, patients treated with anti-T-cell therapies or with ≥1 mg/kg prednisone equivalent should be treated at lower thresholds of DNAemia than patients with minimal risks for CMV disease.

As shown in Table 87.3, preemptive therapy is initiated with an induction dose level of drug used for a minimum of 2 weeks, and this is followed by a maintenance period with reduced dose that can vary in duration from an additional 2 weeks, necessary to bring CMV to an undetectable level, or continued through the period of maximum immunosuppression to day 100 [2,5]. CMV infection will clear in most patients within 2 weeks, but for those with stable or increasing CMV levels, the induction period should continue. Maintenance therapy begins with clearance of CMV and consists of ganciclovir or valganciclovir as shown in Table 87.3 and given for 5–7 days per week for an additional period based on the patient's risk factors. For example, if the CMV blood levels are negative ×2, and the subject is not receiving corticosteroids for GVHD treatment, then maintenance can stop. For patients at higher risk for CMV disease, such as those on immunosuppressive medication for acute or chronic GVHD, treatment should continue for up to day 100 post-HCT or even longer depending on risk status. Monitoring for CMV should continue for at least 1 month, and longer for the patient with risk for late disease. The highest risk group meets all of these criteria: (1) matched HCT recipient with continued GVHD or non-matched HCT recipients irrespective of GVHD status, (2) recurrent episode of CMV infection after preemptive therapy, and (3) lymphopenia at day 100 post-HCT or D^-R^+ CMV serostatus [16], but recipients of haploidentical, UCB, or T-cell-depleted HCTs should be considered for prolonged monitoring [2,5]. Recurrent infection requires treatment resumption using the induction/maintenance regimen as before until the virus clears.

General prophylactic treatment strategies for prevention of CMV after HCT

Not all HCT recipients will do well with preemptive anti-CMV management, and failure of preemptive therapy occurs in those at the highest risk for CMV infection [5]. These high-risk groups include haploidentical, UCB, or T-cell-depleted HCT recipients. For these patients, the alternative approach for prevention of CMV is to treat everyone with an anti-CMV agent during the period of risk, namely from the onset of HCT until engraftment is secure and immunosuppressive medications are minimal. Ganclovir, high-dose acyclovir, and valacyclovir have been shown in randomized studies to be effective in CMV prophylaxis

High-dose acyclovir or valacyclovir is usually used during the period prior to stable engraftment, and then ganciclovir is used [2] (see Table 87.3 for dosing recommendations). In a blinded, controlled evaluation of high-dose acyclovir, recipients of matched related or unrelated HCT were randomly assigned to receive either (i) high-dose acyclovir for 6 months (500 mg/m^2 intravenously three times daily) from day −5 to day +30 post-HCT and then oral acyclovir (800 mg four times daily) or (ii) the same high-dose acyclovir for 1 month, or (iii) a standard herpes simplex prevention regimen for 30 days (400 mg orally four times daily) [17]. The use of high-dose acyclovir for 30 days or for 6 months were both associated with reduced CMV infection compared with standard-dose acyclovir.

When ganciclovir is used for general prophylaxis, CMV infection can be significantly reduced, but there is no difference between control and treated groups in terms of mortality. This lack of effect on mortality is different from the effect observed with preemptive use of ganciclovir [13], and this is likely due to the side effects of ganciclovir, which produces neutropenia with increased risk of infection [18]. Because of the toxicity of these agents and their expense, general use of ganciclovir in all CMV-seropositive persons is currently not recommended [5].

A risk-adapted strategy has been described in which patients with GVHD requiring increased corticosteroid therapy were given a 2-week course of ganciclovir. Using this approach, there was no CMV disease and no neutropenia was observed [19]. This has been applied to other HCT populations at high risk for CMV infection, including in vitro or in vivo T-cell depletion, matched-unrelated or haploidentical HCT, or UCB transplantation. Similarly, the risk for CMV disease can increase during the course of any allogeneic HCT owing to significantly increased immunosuppression, and here the method of risk-adapted general prophylaxis should be applied.

The risk for CMV in UCB is among the highest rates of HCT recipients (see Table 87.2) with a corresponding increase in CMV disease [20,21]. For this reason, a prophylactic strategy usually includes high-dose acyclovir or valacyclovir followed by ganciclovir/valganciclovir at engraftment or at the time of first CMV infection (see Table 87.3 for dose recommendations). A recent intensive prophylactic program was reported in which ganciclovir was administered before transplantation from day −8 to −2 pre-UCB, followed by high-dose acyclovir post-transplant with biweekly monitoring for CMV with PCR-based preemptive therapy [22]. This method, although not affecting survival, resulted in lower CMV DNAemia, less use of preemptive ganciclovir, and less CMV disease [22]. Despite the prophylactic method chosen for use in the UCB recipient, the incidence of CMV infection can be expected to be ~50–60% [21,22].

Specific issues in CMV infection prevention

When should preventive strategies be used for autologous HCT recipients?

All CMV-seropositive recipients of HCT are at risk for CMV reactivation, and in the autologous HCT population, the rate of reactivation ranges from 25 to 45% with CMV disease occurring in 2–10% [6]. However the risk for disease in this group is low and is related to conditioning with TBI, use of CD34$^+$-selected T-cell-depleted peripheral blood progenitor cells, and prior use of alemtuzumab, fludarabine, or 2-chlorodeoxyadenosine [2]. Autologous HCT recipients with these risk factors should be managed with preemptive monitoring and early treatment with ganciclovir [5].

Table 87.3 Use of Anti-Cytomegalovirus Antiviral Agents

Drug	Mode of action	Dose	Duration	Comments
Ganciclovir	A synthetic nucleoside analogue of 2′-deoxyguanosine that inhibits CMV DNA polymerase	Induction regimen[a]: 5 mg/kg 2 × daily IV;	14 days or until DNAemia clears	Associated with neutropenia and anemia; interacts with probenecid and mycophenolate mofetil
		Maintenance therapy: 5 mg/kg once daily	Variable based on immune status	
Valganciclovir	Orally available valine ester of ganciclovir; same mode of action	Induction regimen[a,b]: 900 mg twice daily PO;	14 days or until DNAemia clears	Same as ganciclovir
		Maintenance therapy: 900 mg once daily PO	Variable based on immune status	
Foscarnet	An anion pyrophosphate inhibitor of CMV DNA polymerase	Induction regimen[a]: 90 mg/kg twice daily IV;	14 days or until DNAemia clears	Associated with nephrotoxicity and altered Ca^{2+}, Mg^{2+}, K^{+}, and phosphate levels
		Maintenance therapy: 90 mg/kg once daily IV	Variable based on immune status	
Cidofovir	A synthetic nucleoside analog of deoxycytidine that inhibits CMV DNA polymerase	Induction regimen[a]: 5 mg/kg once weekly IV;	14 days or until DNAemia clears	Associated with nephrotoxicity
		Maintenance therapy: 5 mg/kg once in 2 weeks IV	Variable based on immune status	
Acyclovir[e]	A synthetic nucleoside analog of guanosine that inhibits virus DNA replication	High-dose regimen[c]: 500 mg/m^2 3× daily IV or 800 mg 4× daily PO, or 600 mg/m^2 4× daily	Variable based on immune status	Used only for prophylaxis
Valacyclovir[e]	Orally available valine ester of acyclovir; same mode of action	High-dose regimen[d]: 0.5–2 g 3× daily PO	Variable based on immune status	Used only for prophylaxis

[a] The induction dose is intended to clear infection from blood in preemptive management and from tissue during treatment of CMV disease. For CMV pneumonia, add IVIg 0.5 g/kg every other day for 10 doses and then weekly until pneumonia resolves.

[b] Pediatric dose of valganciclovir: induction regimen 15–18 mg/kg twice daily PO; maintenance therapy 15–18 mg/kg once daily PO.

[c] Pediatric dose of acyclovir: 500 mg/m^2 3× daily IV or 18 mg/kg 5× daily PO.

[d] Pediatric dose of valacyclovir: for weight 20–40 kg, 500 mg 3× daily; weight <20 kg, use IV acyclovir.

[e] Not approved for prevention of CMV infection. When used, routine CMV surveillance is required with duration to 80–100 days post-HCT or until CMV DNAemia occurs.

What is the optimal assay for detecting CMV?

The preemptive management strategy places a burden on the transplant team to monitor and detect CMV infection before it progresses to overt disease, and clearly the window of opportunity for such early treatment varies with the sensitivity of the assay. As noted in Table 87.1, there are four general types of assays for the detection of CMV: culture-based assays, antigen assays, and DNA or RNA assays. The tissue culture assay for CMV, called the "shell vial" assay, is rarely used today because it becomes positive later after HCT [5]. Using DNA/RNA-based methods, detection of CMV in blood can be made at a median time of approximately 35 days post-HCT [15,23,24]. Hence the DNA/RNA-based assays widen the opportunity for early treatment by 1 week. Although this seems small, there is evidence that this earlier treatment of CMV infection was sufficient to reduce CMV disease and overall mortality significantly [23]. Also important, the quantitative aspects of these tests allow them to be useful for monitoring the response to treatment.

When should ganciclovir and foscarnet be used together?

There has been no evaluation of dual ganciclovir and foscarnet therapy for CMV disease or for CMV treatment failure. However, it has been shown that for recipients at high risk for CMV disease, foscarnet and ganciclovir could be used in combination as preemptive therapy [25]. In this method, during maintenance therapy, these drugs were used on alternate days. Because of the potential for induction of resistance, however, the alternate-day use of an anti-CMV agent cannot be recommended.

When should cidofovir be used in the HCT recipient?

Cidofovir has been used for the preemptive management of the HCT patient [26]. As shown in Table 87.3, the dosage for cidofovir is 5 mg/kg per dose in two doses give 1 week apart, followed by maintenance therapy provided every other week. The drug is given with probenecid and adequate preinfusion hydration. In the United States, cidofovir is not approved for the prevention of CMV infection in the HCT recipient. It is nephrotoxic, and its use in the HCT setting remains a third-line approach when preemptive use of ganciclovir or foscarnet has failed.

CMV-associated diseases after HCT

Diagnosis of CMV-associated infection and disease

The clinical course of CMV infection involves a spectrum from earliest detected infection to specific signs and symptoms as the virus reactivates from latency and expands and spreads to involve specific organs. Today, a quantitative DNA PCR or CMV antigenemia assay is most commonly used clinically; positive results occur at expected times post-HCT, with anticipated clearance during antiviral therapy (see Table 87.1).

The diagnosis of CMV-associated end-organ disease has requirements that have been described [27]. Since CMV is a ubiquitous virus based on its presence in blood elements, it is important to use these definitions. For each end-organ infection, it is essential that there be a combination of signs/symptoms of disease and laboratory detection of CMV in tissue material. The signs/symptoms would be related to lung, intestine, liver, brain, retina, and so on, and the laboratory detection would be virus isolation, tissue biopsy analysis by histopathology, immunohistochemical staining, or in situ hybridization. CMV antibody and DNA PCR are not appropriate for confirmation of end-organ disease because antibody production is not reliable post-HCT during periods of immunosuppression and because DNAemia can contaminate a tissue specimen and cause a false-positive test [27].

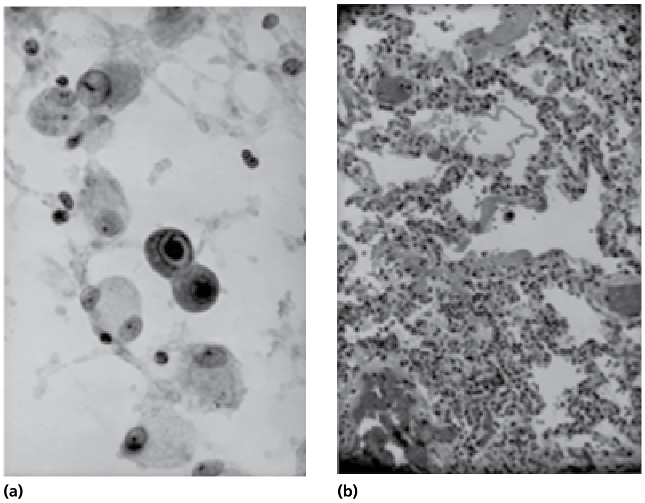
CMV-associated pneumonitis

CMV-associated pneumonia is defined as a progressive interstitial pulmonary process, as evidenced by hypoxia and by lung imaging, with simultaneous evidence of CMV infection in the lung and without evidence for other causes of pneumonitis. Prior to the development of antiviral methods for the prevention of CMV infection, CMV-associated interstitial pneumonia (CMV-IP) occurred in 15–30% of HCT allograft recipients. Today, with the availability of methods to prevent CMV-IP, the disease is rare and usually appears in late-stage patients with poor immune reconstitution or chronic GVHD [15,16].

Bronchoalveolar lavage (BAL) is the preferred method of diagnosis of CMV-IP, and the specimen should be analyzed for infectious virus and for cytological evidence of CMV. As shown in Figure 87.2b, inclusion bodies typical for CMV can often be seen in CMV-positive BAL samples. No matter when CMV-IP occurs after HCT, hypoxia is the major physiological abnormality observed and, as illustrated in Figure 87.2a, the histopathology of CMV-IP involves thickening of the interalveolar membranes with cellular infiltrates and edema. The radiologic abnormalities suggestive of interstitial pneumonitis can be seen on X-ray films even without more advanced imaging (Figure 87.3). However, computed tomography (CT) imaging will demonstrate earlier findings with heterogeneous mixed areas of ground-glass opacity, small centrilobular nodules, and consolidation. The differential diagnosis includes radiation-induced pulmonary disease, cytotoxic chemotherapy-induced pulmonary damage, pulmonary hemorrhage, pulmonary edema, metastatic neoplasia, and other infections of fungal, viral, or bacterial etiology.

CMV-associated enteritis and other organ-specific diseases

CMV enteritis is defined as an enteropathic syndrome with pain, nausea and vomiting, diarrhea, and evidence of CMV infection at the site of an inflammatory or ulcerative mucosal lesion. Gastrointestinal syndromes associated with CMV are the most common CMV-related medical problems in the allogeneic HCT



(a) (b)

Figure 87.2 Histopathology of cytomegalovirus interstitial pneumonia (CMV). (a) Photomicrograph of thin section of lung from a patient with CMV-IP stained with hematoxylin and eosin. Note the cell in alveolar space containing Cowdry type A intranuclear inclusion typical of CMV. Magnification ×640. (b) Photomicrograph of Papanicolaou-stained bronchoalveolar lavage specimen from a patient with CMV-IP. Note similar CMV-induced "owl's eye" intranuclear inclusions. Magnification ×1000.

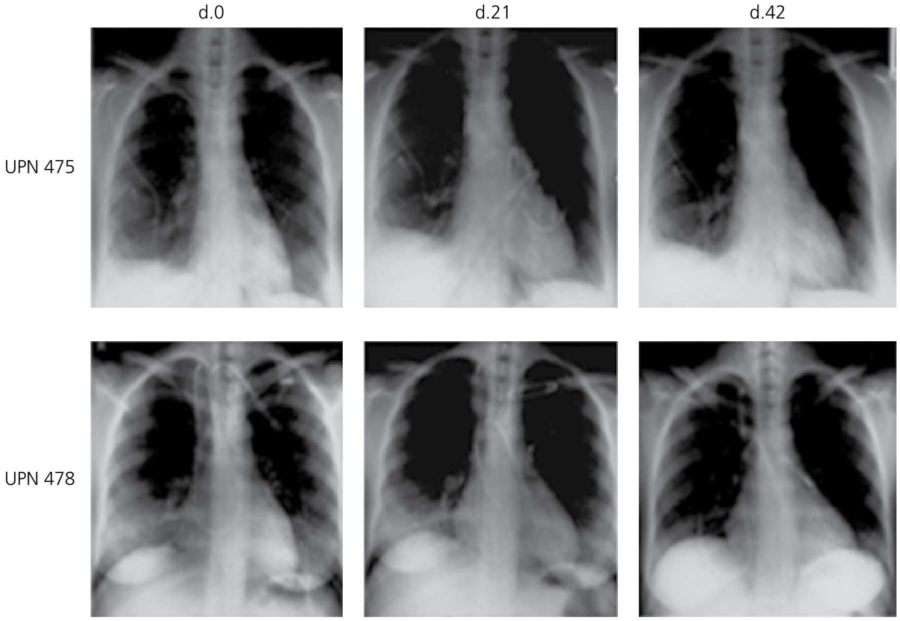


Figure 87.3 Clinical course of treated cytomegalovirus (CMV)-interstitial pneumonia. This is a series of X-ray films from two patients (UPN475 and UPN478) treated with ganciclovir as described in Table 87.3; radiographs are from days 0, 21, and 42 of treatment. Note the resolution of the right lower lobe pneumonitis in both patients.

recipient but are not associated with altered survival outcome [15]. Ulcerations associated with CMV infection can be identified in the esophagus, the stomach, the small bowel, and the large intestine. The diagnosis is made by the association of CMV infection with mucosal pathology and appropriate symptoms [27]. The median onset of CMV enteritis is 91 days post-HCT (range 17–527 days) and a 2-year overall survival rate in this population of 35% [28]. CMV enteritis must be distinguished from gastrointestinal GVHD by appropriate endoscopic and histopathology.

Other CMV-associated syndromes

Since the majority of at-risk HCT recipients will reactivate CMV infection, the accurate association of other syndromes with this infection can be difficult. As noted already, organ-specific diagnosis of CMV infection must be based on tissue-based evidence of CMV infection [27]. In addition to mononucleosis-like syndromes with fever, arthralgia, and malaise, both hepatitis and suppressed marrow function including neutropenia and thrombocytopenia have been associated with acute CMV infections. The course of reactivated CMV infection without organ-specific signs is not well described in the allogeneic HCT recipient, but febrile episodes can be a significant part of this infection. In general, other CMV-associated organ-related syndromes, such as hepatitis and even encephalitis, are better defined as syndromes with specific organ dysfunction and concomitant presence of active CMV infection.

Treatment of CMV-associated diseases

Therapy of CMV-associated interstitial pneumonia (CMV-IP)

The treatment of CMV-IP has had mixed success in immunocompromised persons, probably due to variations in patient groups, viz., different hematologic diagnoses, different levels of immunosuppression post-HCT, and varying contributions from host factors, known and unknown, that modify protection from CMV infection. Historically, the outcome for the untreated disease was very poor until the availability of ganciclovir, but even when ganciclovir was used alone, at doses ranging from 7.5 to 15.0 mg/kg/day, outcome was uniformly poor [29]. Thus, unlike the initial experience in the use of ganciclovir for treatment of CMV diseases in AIDS patients, in which prompt clinical response was the rule, ganciclovir alone was not able to improve the outcome of CMV-IP in the HCT recipient. It was not until the combined use of ganciclovir with CMV antibody-enriched intravenous immunoglobulin (CMV-IVIg) that improved outcome of CMV-IP was observed . This method used ganciclovir at 10 mg/kg daily and IVIg 500 mg/kg every other day for 21 days, followed by ganciclovir at 5 mg/kg daily 5 days per week and IVIg at 500 mg/kg weekly until day 180 after HCT [30]. Ganciclovir plus IVIg continues to be the recommended treatment for CMV-IP (see Table 87.3), yet it still meets with only varying success, probably owing to variations in patient-related factors. For example, patients who do not receive TBI compared with those who do have significantly improved outcome and, in general, patients with multiple organ dysfunction or respiratory failure are less likely to respond to antiviral therapy [31].

During treatment, a repeat BAL is suggested after the initial 21 days of treatment if there is any question regarding response to the initial antiviral therapy. The duration of maintenance therapy varies but is usually continued for the duration of major immunosuppressive treatment. Fever and hypoxia usually resolve within the first week of treatment, but X-ray changes can persist for many weeks. The patient with a slow response to treatment or having deteriorating pulmonary function on treatment prompts the consideration of ganciclovir-resistant CMV, or the presence of secondary infections , and both of these questions can be addressed by repeat BAL. CMV infection is usually eliminated from the lavage specimen by 21 days after the start of treatment, and any deterioration of pulmonary function with continued CMV lung infection should prompt a work-up for antiviral drug resistance (see below).

If ganciclovir resistance occurs, or if ganciclovir cannot be used because of marrow toxicity, then foscarnet is indicated. As shown in Table 87.3, foscarnet is given at a dose of 90 mg/kg twice daily with saline infusion over 2 hours during the initial induction period. Alternatively, a regimen of 60 mg/kg three times daily can be used. Maintenance therapy follows this at a dose of 90 mg/kg per day for an indeterminate period, as determined by the immunosuppression of the patient and the response to therapy. Foscarnet is nephrotoxic, and it is recommended that the calculation of the dosage be determined by creatinine clearance, with appropriate attention to hydration and electrolyte balance. There has been no systematic evaluation of the efficacy of foscarnet plus immunoglobulin for the treatment of CMV-IP.

Therapy for CMV-associated enteritis and other syndromes

A controlled study using ganciclovir has shown that despite antiviral effects, there was no significant improvement of CMV gastroenteritis [32]. Nevertheless, because of its antiviral effect, it is common practice to use ganciclovir without IVIg for CMV enteritis according to the dosing schedule shown for CMV-IP (see Table 87.3). For other CMV-associated syndromes such as hepatitis, retinitis, and CMV-associated marrow suppression, the same regimen as shown in Table 87.3 is used.

Complications of CMV therapy

The major complications associated with ganciclovir treatment are neutropenia and serum creatinine elevation. Analysis of patients with ganciclovir-associated neutropenia has indicated that risk factors include elevated bilirubin level (≥6 mg/dL) during the first 20 days after HCT, a serum creatinine level of ≥2 mg per dL after day 21 post-transplantation, a low marrow cellularity between days 21 and 28 post-HCT, or a low white blood cell (WBC) count at time of ganciclovir initiation [18,33]. Of importance, this treatment-related neutropenia is an independent risk factor for poor overall survival [relative risk (RR) 3.8, $p = 0.001$], for poor event-free survival (RR 2.1, $p < 0.0001$), and for relapse (RR, 1.7, $p = 0.03$) [18]. Therefore, in the event of ganciclovir-induced neutropenia unresponsive to granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF), ganciclovir/valganciclovir therapy should be switched to foscarnet. To minimize this problem, a stopping rule for ganciclovir use is invoked when the absolute neutrophil count is lower than 1000/μL on two consecutive days.

Antiviral drug resistance

Breakthrough CMV infection is not uncommon while on seemingly adequate antiviral therapy and is not an indication of treatment failure [34]. Studies have shown that approximately 15–25% of patients treated preemptively with ganciclovir or foscarnet will require later retreatment for recurrence [23]. As noted, ganciclovir resistance is uncommon , and rising CMV DNA levels or the presence of recurrent CMV infection are the best guide for suspecting true antiviral drug resistance. The signature mutation for ganciclovir resistance occurs in the CMV gene UL97 that encodes a phosphotransferase enzyme necessary for activating ganciclovir to its active phosphorylated form or in the CMV DNA polymerase gene UL54 [35]. In a recent study of approximately 150 CMV infections in transplant recipients in Copenhagen, none had a genetic mutation suggestive of ganciclovir resistance at first detection of CMV, but at recurrence, 37% had such a mutation [36]. Hence early CMV infection, even when clearance of plasma DNAemia is delayed, is not an indication for ganciclovir resistance, but failure to resolve DNAemia during recurrent infection suggests drug resistance. Confirmation of drug resistance is done by phenotypic or genetic analysis of CMV-positive blood [35]. Forcarnet resistance has rarely been observed in HCT but when seen is due solely to mutations in UL54 [37], and dual resistance of CMV to both forcarnet and ganciclovir has occurred. Therapeutic decisions usually have to be made in the absence of definitive evidence of drug resistance, and foscarnet should be substituted in place of ganciclovir in the following situations: (i) whenever there is marrow toxicity and the CMV assays remain persistently positive or show rising CMV DNAemia, (ii) when persistent or recurrent infection is present, especially at the time of increased treatment of GVHD with corticosteroid or other secondary anti-GVHD drugs, and (iii) when there are changing clinical signs suggestive of CMV disease.

Use of cidofovir in the setting of CMV treatment failure has been reported [26] and remains an alternative therapy. However, because of the potential for cross-resistance with ganciclovir, genetic testing should be carried out in association with such use. Although not yet available commercially, an orally available prodrug of cidofovir, brincidofovir, may become useful in the management of drug-resistant CMV (see below).

Cellular Immunity to CMV

CMV reactivation is initially controlled by the innate immune system and extension of infection to organ-specific disease is prevented by the adaptive immune system (see review [38]).

Innate immunity

The importance of NK cell protection from CMV infection was first suggested by the occurrence of repeat CMV infection in patients with NK cell deficiency [39]. CMV infection and the innate immune system are mutually involved in a remarkable system of maturation and control. The NK cell receptor system is complex and ranges from killer immunoglobulin-like receptors (KIRs) that bind to HLA molecules, to immunoglobulin binding CD16, to CD94:NKG2 receptors that bind lectins [40], and other pathogen recognition receptors (PRRs) on NK cells that recognize CMV [41,42]. These components of the "resistome" have been shown to be particularly important in the control of murine CMV [43], and there is expanding but incomplete understanding of how this complex innate immune system is modulated by and protects from human CMV [38,42]. When CMV first binds and enters a cell, there is initiation of events that upregulate the expression of nuclear factor kappa B (NFκB) and interferon regulatory factor 3 leading to expression of inflammatory cytokines. TLR2, which senses glycopeptides and lipopeptides, can recognize CMV surface glycoproteins gB and gH, and it is responsible in part for this cytokine upregulation [44]. TLR2 and TLR3 have been shown to be expressed on NK cells, and CMV activation of NK cells in vitro can be partially blocked by anti-TLR2. It is thought that, in association with cytokines such as IL-12 or type I interferons, activation by TLR agonists leads to enhanced NK effector function. TLR2 polymorphism R753Q has been associated with increased CMV infection and disease after HCT [45]. TLR3 polymorphism L412F appears more frequently among patients with chronic mucocutaneous candidiasis who have increased CMV infection, and among allo-HCT patients, polymorphisms in TLR9 have been associated with increased CMV infection [46,47]. In the murine model of CMV, multipleTLR genetic variants have been associated with loss of protection [43], and it is possible that as we gain a better understanding of the role of TLRs in allo-HCT, TLR polymorphisms will be linked as risk factors for CMV infection and disease.

Early post-HCT, NK cells are the major donor lymphoid cells to appear, and these NK cells express predominantly an inhibitory receptor CD94-NKG2A, which is associated with low cytotoxic function and little expression of KIRs [48]. At this point, control of CMV infection appears to be under the aegis of three immune mechanisms: first, the priming of cytokine release by PRRs as noted above; second, the maturation or education of the NK cells to a more functional cell; and third, the enhancement of adaptive immunity by these innate processes. The proportion of KIR$^+$ NK cells normalizes by cell differentiation, and the function of these KIR$^+$ cells is linked to corresponding HLA ligands [49]. CMV infection appears to play a role in this maturation, as seen by the expansion of NK cells positive for CD94-NKG2C, an activating receptor (see review [42]). The CD94-NKG2A phenotype is altered in association with CMV infection, by unknown processes, to the more mature NK phenotype, which then persists as NKG2C$^+$ NK cells that not only are more functional as measured by granzyme B expression and CD107a, interferon-gamma (INF-γ), and tumor necrosis factor-alpha (TNF-α) release, but also express KIRs specific of HLA class I [50]. This event is recapitulated in HCT in CMV-positive recipients following reactivation of CMV infection [51]. This is analogous to the persistence of Ly49H$^+$ murine NK cells, which expand in response to murine CMV and protect from reinfection [52]. hence it is hypothesized that under the influence of CMV, NK cells mature and develop a heightened function with "memory" NK cells [53]. In the mouse model of CMV, adoptive transfer of such cells provides protection from infection [53]. It remains to be determined in human CMV whether NK cells can recognize viral polypeptides in a similar manner.

NK cell KIRs consist of surface receptors termed activating (aKIRs) and inhibitory (iKIRs) receptors (see review [54]). The iKIRs encode receptors that recognize HLA class I molecules and block further interaction with "self," and this provides a mechanism for NK cell tolerance [40,41]. In healthy individuals, this system of aKIRs and iKIRs regulates cytotoxic functions important in both tumor recognition and viral infection. When the KIR and its ligand are present, the NK cells are "licensed" to function in providing either an inhibitory signal to extinguish cytotoxicity or an activator signal to accelerate cytotoxicity. This is of particular interest in allogeneic HCT where there is the potential for the newly engrafted donor cells to have a KIR–ligand mismatch when a ligand is absent from the genotype, a so-called "unlicensed" state. This can influence the outcome of allogeneic HCT in conflicting ways by affecting GVHD, leukemic relapse, and even survival [40,55]. Clinical benefits are seen when donor NK cells encountering recipient target cells that lack the HLA class I ligand mediate an antileukemic effect [56]. It remains to be determined how this can best be exploited in donor selection pre-HCT.

With regard to CMV infection, KIR haplotypes have been associated with a significant reduction in CMV reactivation [57]. The presence of additional activating KIR genes or identity between donor and recipient aKIR genotypes has also been associated not only with decreased CMV reactivation, but also with improved survival [58]. A donor aKIR profile predictive of low risk of CMV reactivation has been described [59]; however, similarly to the anti-leukemia effects noted above, it appears that the absence of ligand is most important for control of early infection. In the murine model of CMV, it is the unlicensed NK cells that are protective, even when used adoptively [60]. Similarly, it has been shown that in the setting of allogeneic HCT, the risk of CMV infection is associated with donor KIR genes only when the specific HLA-C ligand is absent from the shared donor/recipient genotype [61]. Thus, unlicensed iKIRs appear to suppress protective responses and increase the risk of CMV infection and unlicensed aKIRs significantly reduce the risk of infection. Consistent with the NK disarming model of Raulet and Vance [62], in the first 100 days post-HCT the HLA ligand appears to serve as a gatekeeper of inherent NK cell function such that, with ligand, KIR-mediated activity is held in check and, without ligand, KIR activity is unrestricted. The consequences of this for the management of HCT patients remain to be determined.

T-cell immunity

T-cell immunity to CMV involves a complex relationship between virus and host with multiple antigens recognized by the host and several immune-escape mechanisms encoded by the virus (see review [38]). As noted over three decades ago, cytotoxic T-lymphocyte (CTL) function is most critical for protection from severe disease and mortality in the setting of HCT [63], and HLA-restricted CTL function was associated with survival from CMV-IP [64]. Subsequently, using new methods of quantifying CMV-specific cellular mediated immunity (CMI), studies demonstrated that patients lacking CD4-specific CMV recognition were at greater risk for CMV complications [65]. Recipients with D^+R^+ CMV serostatus have better multifunctional recovery of CMV-specific $CD8^+$ T-cell immunity and require less anti-CMV therapy [8]. Immunologic recovery of CMV-specific cellular immunity by 3 months post-HCT is a critical factor in protection from CMV infection, and the factors that indicate that a recipient is at high risk for CMV due to impaired cellular immunity include the use of high-dose corticosteroids, defined as >1 mg/kg per day, $CD4^+$ cell count $<100 \times 10^9$/L, and $CD8^+$ cell count $<50 \times 10^9$/L [2].

The two predominant immunologic targets of CMV-specific CMI are CMV pp65 and CMV-IE (see review [66]), yet there is a wide range of responses to CMV proteins [67,68]. Analysis of T-cell receptor (TCR) usage among such peptide-specific responses permits quantitative measure of CMI, and applying this technology to HCT recipients during the early expansion of $CD8^+$ lymphocytes, those patients developing at least 10^7 CMV-specific $CD8^+$ cells/μL appeared to be protected from CMV disease. Failure of immune reconstitution to this level within the first 65 days post-HCT is a risk factor for CMV complications [69]. Patient groups could be dichotomized into those with rapid immune recovery (≥7 CMV-specific $CD8^+$ T cells/μL) and those with delayed recovery at 65 days (<7 CMV-specific $CD8^+$ T cells/μL), with the latter group at risk for recurrent infection and disease [69].

Future developments relating to CMV infection in HCT

CMV infection and protection from leukemic relapse

The interaction of CMV and the immune system provides a hypothesis that infection might induce activation of innate processes that are protective in non-specific ways. The observation that CMV can activate NK functions, which then remain for long periods [42], supports such speculation. In this regard, it was shown almost 30 years ago that HCT recipients with CMV reactivation had less leukemia relapse that non-reactivators [70]. Epidemiologic studies have varied in regard to CMV seropositivity and risk of relapse, with some showing that seronegative transplants were at greater risk [70,71]. However, a large population analysis recently showed no difference in relapse-free survival at 2 years post-HCT based on CMV serologic status [72].

Recently, however, there have been several reports that CMV reactivation is associated with protection from relapse during the first year post-HCT [73–75]. Of note, there is differing duration of the putative protective effect of CMV infection versus no CMV. Elmaagacli et al. studied 266 acute myeloid leukemia (AML) patients and reported a significant reduction in relapse (9% vs. 42%, respectively) at 10 years' follow-up [73]. Green et al. studied 2566 patients, including AML, acute lymphoblastic leukemia (ALL), chronic myelogenous leukemia (CML), lymphoma, and myelodysplastic syndrome (MDS), and reported a protective effect only in AML and only to day 100 post-HCT [74]. In the report of Manjappa et al., 264 AML patients were studied and CMV reactivation was associated with decreased relapse that was sustained for the overall group and for those with myeloablative (MA) conditioning [75]. Those with reduced intensity conditioning with antithymocyte globulin (ATG) had more CMV reactivation than did the MA group and a relapse rate that was similar to those with no CMV infection. In addition, similarly to the large sero-status study of Schmidt-Hieber et al. [72], an increased non-relapse mortality in the CMV-infected group was observed in two of these studies [74,75]. These studies were retrospective, and prospective studies are warranted to confirm a CMV-based protective effect on relapse. More importantly, if this is a function of the conditioning regimen, it is possible to design studies to determine what aspects of conditioning influence this protection. It is interesting to hypothesize that the known effects of CMV on activation of innate immunity could play a role here, but it will be equally important to determine the removal of the effect of CMV on non-relapse mortality. Ideally, it might eventually be possible to maintain an activation of the NK system similar to that provided by CMV but without the deleterious aspects of CMV in the HCT recipient.

Improved antiviral agents for CMV

The current US Food and Drug Administration (FDA)-approved CMV-specific antiviral agents have improved management of the allogeneic HCT recipient and better post-transplant GVHD prophylaxis appears to have enhanced this improvement [76]. However, the available antiviral treatments are less than optimal because of their toxicity and because most are not orally bioavailable. Maribavir is an orally bioavailable drug that acts by blocking the nuclear egress of CMV virions by inhibiting CMV UL97-mediated phosphorylation of nuclear lamin A/C and possibly US27. In a large phase III trial, 681 patients were recruited from 90 centers in Canada, the United States, and Europe, and maribavir failed to show efficacy when used prophylactically to prevent CMV disease. The results illustrated the importance of understanding CMV risk factors in the design of antiviral studies on HCT recipients [77]. Two new agents, brincidofovir (also known as CMX001) and letermovir (also known as MK-8228), are promising oral agents that, if safe and effective for prophylaxis of CMV, could change the management of CMV.

Brincidofovir is an orally bioavailable prodrug of cidofovir that was developed as a lipid conjugate of the synthetic nucleotide analog cidofovir with 400-fold greater in vitro potency against

CMV. It is absorbed in the small intestine where it is converted intracellularly to the active form, but, unlike cidofovir, it is not concentrated in the renal tubules and lacks the same renal toxicity. In a phase I dose-escalation study of the drug used prophylactically in 230 allogeneic HCT recipients, brincidofovir at a dose of 100 mg twice weekly significantly reduced the incidence of CMV infection compared with placebo (37% vs. 10%, respectively) [78]. Myelosuppression and nephrotoxicity were not observed, but diarrhea and other abdominal symptoms were dose limiting at 200 mg twice weekly. A phase III evaluation of brincidofovir is in progress (Trial NCT01769170).

Letermovir is an orally bioavailable agent that acts to inhibit CMV by a novel mechanism targeting CMV UL56/UL89, an enzyme important in the cleavage of virus DNA into unit-length genome size that permits packaging into new virions. Because of the unique mechanism of action, no cross-resistance has been seen with existing anti-CMV agents active against CMV UL54 DNA polymerase, namely ganciclovir, foscarnet, and cidofovir. Letermovir was studied as preemptive treatment in 27 kidney transplant recipients found to have CMV DNAemia; nine patients each received either 40 mg twice daily, 80 mg once daily, or standard treatment (SOC) [79]. The drug was safe, with no serious adverse events, had plasma trough levels consistently above concentrations needed for in vitro CMV inhibition, and CMV DNA clearance from blood not different from the SOC group.

CMV vaccines

A vaccine that could establish adequate T-cell immunity for protection from CMV infection has been a long-standing goal. Vaccines have targeted antibody production using CMV gB glycoprotein plus adjuvant [80] or T-cell immunity using CMV DNA or polypeptides [81,82]. Induction of anti-gB antibody in solid organ transplant patients was associated with shorter duration of DNAemia and fewer days of ganciclovir treatment [80]. In a phase II placebo-controlled trial of a CMV DNA vaccine (ASP0113, formerly TransVax, Vical/Astellas Pharma) encoding CMV pp65 and CMV-gB proteins in a poloxamer-based formulation involving 74 allogeneic HCT recipients, the vaccine reduced the occurrence, recurrence, and duration of CMV DNAemia [81]. However, the rates of clinically significant DNAemia requiring ganciclovir therapy were not different from placebo. ASP0113 is now in phase III development (Trial NCT01877655). Finally, a vaccine in which a CD8-specific CMV pp65 peptide epitope is fused to a helper cell epitope and used with a TLR9 agonist has been shown to be safe and immunogenic in volunteers [82] and is now being evaluated in allogeneic HCT recipients (Trial NCT01588015).

T-cell Immunotherapy for CMV infection

The first adoptive transfer of CMV-specific T cells was carried out more than 20 years ago [83] and, despite a positive outcome, this therapeutic method required limiting dilution cloning and was technically challenging to manufacture. In a study of 14 recipients, however, treated at 30–40 days post-allogeneic HCT with these ex vivo expanded CMV-specific donor $CD8^+$ T cells, cytotoxic anti-CMV immunity was enhanced and persisted for at least 12 weeks with no CMV viremia but did required CD4 help for effect [84]. To improve this method, short-term bulk culture of CMV-specific $CD8^+$ T cells, primed with CMV antigen-exposed dendritic cells, was used, and 16 patients were treated with 1×10^5 lymphocytes/kg at the time of CMV DNAemia while preemptive ganciclovir was withheld unless DNAemia increased [85]. Eight patients cleared the DNAemia without further treatment and eight required ganciclovir; two of these had recurrent infection when treatment was stopped [85]. To simplify the method further, CMV-specific CD8 cells were selected from donor blood by magnetic beads and directly injected into HCT recipients at the time of CMV DNAemia [86]. At a median dose of 8.6×10^3/kg, CMV-specific CD8 cells became detectable with 10 days and CMV DNAemia was cleared in eight of nine treated patients [86]. Although simpler in design, the non-availability of clinical-grade CMV-specific magnetic beads has curtailed the development of this method. To overcome this problem, a two-step purification method was developed in which donor cells were briefly primed in vitro with CMV pp65 protein and then IFN-γ-producing cells were isolated by magnetic beads [87]. In 18 treated patients with refractory CMV infection, 15 cleared or considerably reduced the persistent CMV DNAemia, and only one of 13 patients having post-infusion expansion of these T cells died of CMV disease [87]. Three CMV-related deaths occurred in patients in whom there was no expansion of infused T cells. Finally, using $CD8^+$ T cells expanded in vitro after exposure to Epstein–Barr virus (EBV)-expressing B cells previously infected with an adenovirus (AdV) modified to express CMV pp65, this "tri-virus" T-cell product had immune recognition of EBV, CMV, and AdV [88]. In 10 CMV-infected patients treated with the polyvalent T-cell product, all developed increased CMV-specific T-cell immunity as measured by ELISPOT assay, with clinical improvement in most [88]. The tri-virus cell product is currently being evaluated in an expanded access trial (NCT01945619) at Baylor College of Medicine, and a phase II trial using CMV pp65-primed T-cells for CMV disease is active at Memorial Sloan Kettering Cancer Center (Trial NCT01646645).

Conclusion

The availability of antiviral agents has greatly altered the management of the allogeneic HCT recipient, yet control of CMV remains less than optimal because of the toxicity of available agents. Even when used successfully to prevent early disease, the patient often remains at risk for late-onset disease. An immune deficiency underlies prolonged susceptibility to CMV in this population, and this continued inability of the host to develop protective immunity in some patients remains the ultimate challenge for improved treatment. It is possible that antiviral agents alone will never completely solve the problem of CMV infection after HCT. It remains to be determined whether less toxic antiviral agents, vaccines, or adoptive immunotherapy will provide a more effective method for preventing CMV disease after HCT.

CHAPTER 88

Herpes Simplex Virus Infections

Sanjeet S. Dadwal and James I. Ito
City of Hope National Medical Center, Duarte, CA, USA

Introduction

Herpes simplex virus (HSV) type 1 (HSV-1) and type 2 (HSV-2) are members of family *Herpesviridae* and subfamily *Alphaherpesvirinae*. HSV possesses the unique characteristics of latency and reactivation in response to various stimuli [1]. Although fatal infections are uncommon, HSV infection can lead to significant morbidity in the hematopoietic cell transplant (HCT) recipient. In the pre-antiviral prophylaxis era, HSV reactivation occurred commonly (70–80%) in the seropositive HCT recipient in the early post-HCT phase prior to engraftment [2,3]. The reduction in HSV infection is primarily the result of universal prophylaxis with an antiviral agent (acyclovir) following HCT [4,5]. This has become the standard of care across transplant centers. Although the problem of HSV infection has diminished substantially in the early pre-engraftment period, the major problems now are related to the delayed HSV onset after discontinuation of antiviral prophylaxis and antiviral resistance.

Virology

HSV-1 and HSV-2 belong to the genus *Simplexvirus* of the subfamily *Alphaherpesvirinae*. The morphologic appearances of all herpesviruses are similar and are comprised of four structural components: (1) an electron-dense core containing linear double-stranded viral DNA; (2) an icosadeltahedral capsid containing 162 capsomeres and measuring 100–110 nm in diameter; (3) an amorphous layer (tegument) between the capsid and envelope composed of proteins that have important role in the early viral replication on entry into the host cell; and (4) a lipid envelope with glycoprotein spikes [6].

Primary infection occurs when HSV enters the host cell via damaged skin or mucus membrane. This occurs by attachment of the virus to cell surface receptors mediated by various viral glycoproteins (e.g. C, B, and D). This leads to fusion of the viral envelope with the host cell plasma membrane resulting in entry of the nucleocapsid with the tegument in to the cytoplasm. Nucleocapsid releases the viral DNA into the nucleus via nuclear pores. Viral replication then proceeds in the nucleus with transcription, DNA synthesis, capsid assembly, DNA packaging, and formation of the envelope. The process of viral replication is regulated by stepwise expression of viral genes: alpha (α), beta (β), and gamma (γ). The gene products of α gene are regulatory proteins that shut off host protein synthesis and activate expression of β and γ genes. The β gene encodes enzymes involved in nucleic acid metabolism (e.g. thymidine kinase) and DNA synthesis (e.g. DNA polymerase). The proteins expressed by the β gene serve to induce γ gene expression, resulting in the synthesis of structural proteins and nucleocapsid [6]. The end result of primary lytic infection is cell death.

Pathogenesis

HSV is neurotropic and establishes latent infection, two unique properties of *Alphaherpesvirinae* that are central to the pathogenesis and pathology of HSV infection and disease. HSV infection occurs after close/intimate contact of a seronegative individual with someone having subclinical viral shedding or with active disease. The virus enters from mucosal surface or abraded skin, replicates at the site of primary infection [7], and undergoes retrograde transport to the dorsal nerve root ganglia where it multiplies in a small number of sensory neurons, resulting in lytic infection. HSV-1 predominantly leads to oropharyngeal infection and HSV-2 to genital infections. However, either virus can infect the oropharyngeal or genital mucosa. Thereafter, the virus may spread to the mucosal surface or skin with its characteristic vesicular lesions through centrifugal migration via peripheral sensory nerves. After primary oropharyngeal infection, latency is established in the trigeminal nerve root ganglion, and sacral nerve root ganglion in cases of primary genital infection. Other dorsal root ganglia, such as vagal, geniculate, and superior cervical ganglia, may harbor the virus [6]. In the infected neurons, viral genome exists in an episomal state for the life of the individual. HSV has been retrieved from involved ganglion explanted from cadavers [8]. However, during the latent state, infectious virus can no longer be recovered from the ganglia, although viral DNA can be recovered from some ganglion cells. Although a number of mechanisms have been proposed, the mechanism(s) whereby latency is established and maintained is not well understood [6]. It is likely that the latent infection of the neuron involves intrinsic non-permissive properties of sensory neurons and viral functions, and maintenance likely involves the CD8 T cells [6,9,10]. Latency permits the virus to survive in a sequestered state not vulnerable to the inhibitory effects of antiviral agents or the host's immune system.

Reactivation of HSV from its latent state is a characteristic feature of this infection. A number of stimuli have been closely associated with reactivation: physical or emotional stress, fever, exposure to ultraviolet light, tissue damage, and cell-mediated immune suppression. Many of these risk factors are present in the recipients of HCT in the early and late phases. It is likely that the tissue damage with associated changes in cytokine profile and the repair process may influence reactivation along with immune suppression [11]. Reactivation may result in asymptomatic shedding or clinical

disease. This phenomenon occurred in 82% of seropositive HCT recipients prior to the advent of antiviral prophylaxis [2]. Since the introduction of antiviral prophylaxis, reactivation has declined significantly [3]. In HCT recipients, virtually all HSV infections are related to reactivation of latent virus. The most commonly affected sites include the oropharyngeal mucosa and genital tract. Disseminated disease with visceral organ involvement has been observed in the severely immunosuppressed HCT recipient. The major factor in the pathogenesis of HSV disease in HCT appears to be impaired cell-mediated immune response.

Immunology

General aspects

Innate and adaptive immune responses play an important role in the control of viral infection [12]. Innate immune responses are the first line of defense and have direct antiviral effects. They involve Toll-like receptors (TLRs) (and in HSV infection involve TLR2 and TLR9), natural killer (NK) cells, macrophages, and dendritic cells. TLRs are expressed on various cells including dendritic cells, and mediate interferon production [12]. Increased shedding and reactivation of HSV has been associated with TLR2 polymorphisms [13] and a recent study suggested that polymorphisms in TLR3 may confer resistance to HSV-2 infection [14]. Severe HSV disease has been described in two patients with myelodysplasia who had undetectable NK cells and plasmacytoid dendritic cells in the blood can also suggest the role of innate and acquired immunity in controlling HSV infection in an immunocompromised host [15].

However, it is the adaptive immune response, primarily the cell-mediated immunity (CD4 T cells, CD8 T cells), that is crucial in controlling HSV infection (especially primary infection) [6,16]. This is also supported by the observation that patients with agammaglobulinemia handle HSV infection adequately, and the presence of neutralizing antibody does not prevent HSV reactivation. In contrast, patients with T-cell immune deficiencies (transplant recipients, those infected with human immunodeficiency virus, and congenitally T-cell-deficient patients) tend to have more widespread, invasive, and disseminated disease [17]. In animal models, it appears that T cells play a major role in preventing dissemination of HSV [18], although antibodies can reduce the viral titers. Cytotoxic T-lymphocyte (CTL) response correlates with viral clearance in recurrent HSV infection and is mediated by CD8 T cells with the support of NK cells and CD4 cells [17]. Cytokines also play a role in the immune response to HSV infection, including latency [19].

Immune evasion

HSV can evade and modulate the multipronged host immune response, which in turn enables it to establish latency that subsequently leads to episodes of recurrent infection. It can directly inhibit dendritic cell function, downregulate the expression of major histocompatibilty complex (MHC) I and II molecules, subvert apoptosis of virally infected cells, evade CTLs, avoid antibody-mediated virus neutralization, block antibody-dependent cytotoxicity, and induce the production of immunosuppressive cytokines such as interleukin-10 (IL-10) [6,20].

Immunology in HCT

Almost all of the components of both the innate and adaptive immune system are deficient after the HCT conditioning regimen has been administered [21]. It is probably the combination of mucosal damage, induced by cytotoxic agents of the conditioning regimen, and global but primarily T-cell-mediated immune deficiency that is responsible for the high reactivation rate seen after HCT. Meyers et al. evaluated HSV-specific lymphocyte stimulation responses in patients undergoing HCT in the absence of antiviral prophylaxis [2]. This study identified that the specific lymphocyte transformation responses remained low for the first 40 days following HCT and then returned to pre-HCT levels. The return of the HSV-specific lymphocyte response was independent of the immune status of the donor, acute graft-versus-host disease (GVHD), underlying hematologic disorder, or use of T-cell-depleting agents. However, the immune response correlated with the development of HSV reactivation. Hence it appears that the reconstitution of the HSV-specific immune response requires exposure to antigen in the form of reactivated HSV infection, and passively transferred donor lymphocytes are insufficient to establish immune reactivity in the HCT recipient.

Delayed restoration of HSV-specific lymphocyte responses has been observed when early-onset HSV infections (after HCT) were treated with acyclovir [11]. This delay in response was manifested by frequent HSV recurrences interspersed by shorter intervals between HSV episodes. Similarly, delayed reconstitution was encountered among HSV seropositive patients receiving acyclovir prophylaxis [5]. Not only was reconstitution delayed, but also a significantly lower lymphocyte response was observed in patients receiving acyclovir compared with those on placebo within the first 7 weeks of HCT. This response slowly improved until it matched the placebo group at 3 months after HCT. A more recent study in a group of cord blood (CB) transplantation recipients receiving antiviral prophylaxis demonstrated that HSV-specific T-lymphocyte responses may develop in the first 29–100 days after CB-HCT. The authors concluded that naïve T lymphocytes could contribute to the generation of antigen-specific T-lymphocyte immune reconstitution early after HCT [22]. This is in contrast to earlier studies which suggested that antigen exposure was a prerequisite for early immune reconstitution [5,11]. However, the significance of later versus earlier immune reconstitution is unknown.

Epidemiology

HSV-1 and HSV-2 have a worldwide distribution, and there are no animal vectors or reservoirs. HSV-1 infection predominantly leads to orolabial infection, is more prevalent, and is acquired earlier in life. HSV-2 leads to genital herpes and is transmitted sexually. However, recent epidemiologic investigations suggest increasing rates of genital infection caused by HSV-1 [23].

In recipients of HCT, HSV disease is mostly due to reactivation and the serologic status of the recipient determines the risk for disease, and therefore the need for prophylaxis. The likelihood of any one individual being HSV-1 or HSV-2 seropositive is dependent on a number of factors, including age, gender, race, geographic region, socioeconomic status, and sexual activity. However, once the transplantation is initiated, these factors lose importance and reactivation/disease is a function of the cytotoxic conditioning regimen and immune dysfunction.

Primary HSV-1 infections usually occur in young children under the age of 5 years and are usually asymptomatic. The seroprevalence of HSV-1 slowly increases with age until a 90% rate is achieved by the fifth decade of life [24]. In the United States, African Americans acquire HSV-1 earlier in life. A national survey conducted by the Centers for Disease Control [US National Health and Nutrition Examination Surveys (NHANES)] from 1999 to 2004 estimated the overall prevalence of HSV-1 in US adults at 57.7%, compared with 62% in the period 1988–1994, suggesting a decrease in seroprevalence. In this survey, a higher percentage of individuals with HSV-1 were diagnosed with genital herpes [25]. More recently, this trend of increased genital HSV-1 infection was confirmed in a large clinical trial [23]. The prevalence of HSV-1 antibody inversely correlates with economic status, with a higher prevalence in the lower socioeconomic groups [24,26].

HSV-2 is usually acquired later in life with antibodies beginning to appear in puberty, associated with the initiation of sexual activity. The HSV-2 seroprevalence amongst US adults is approximately 17%, and there has been a downward trend [25]. HSV-2 seroprevalence is higher in women [23]. There is considerable variability of HSV-2 seroprevalence based on ethnicity, with 25% in white women, 20% in white men, 80% in African American women, and 60% in African American men.

In recipients of HCT, 82% of the seropositive patients had HSV reactivation prior to the institution of routine antiviral prophylaxis [2]. The median time to the onset of infection was during the third week after HCT. Approximately 90% of the infections involved orolabial mucus membranes, while 6% had genital infection. Primary HSV infections occurred infrequently and were observed in only 1.5–2% of HCT recipients [2,27]. The incidence of HSV infection has decreased since the introduction of antiviral prophylaxis and onset shifted to a later time period. The incidence of reactivated HSV infection has been reported at 0 and 21% in HCT recipients on antiviral prophylaxis in two separate studies, compared with 70 and 68% in the placebo groups [3,5]. The phenomenon of viral shedding despite antiviral prophylaxis is well described and may contribute to disease development. HSV reactivation tends to occur after cessation of prophylaxis, and in one study was reported to occur at a median of 25 days in 70% [3]. Another study reported reactivation at median of 8 weeks in 38% of the seropositive HCT patients [5]. The development of HSV disease in HCT recipients has been associated with protracted cellular immunodeficiency (such as occurs with haploidentical/T-cell-depleted HCTs) [28], type of HCT (matched unrelated and mismatched) [29], and severity of GVHD [30]. Therefore, multiple factors contribute to the epidemiology of HSV infection in the setting of HCT.

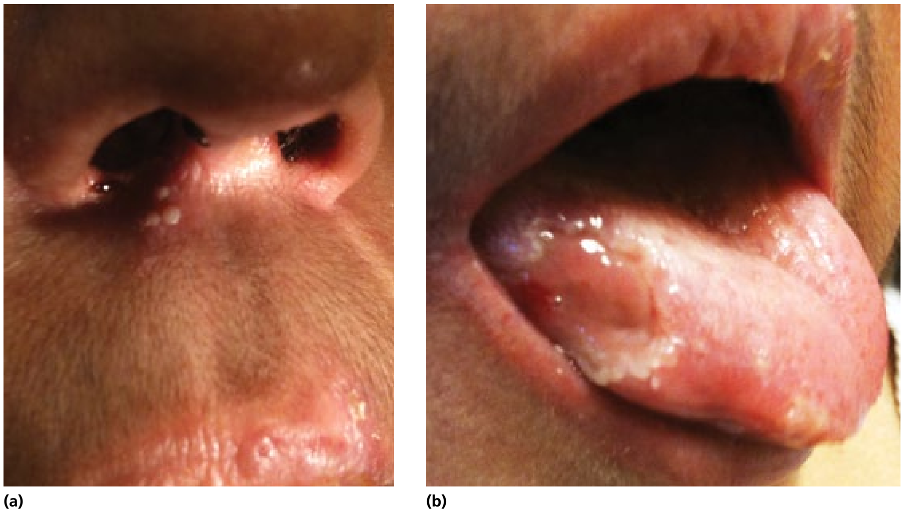
Clinical manifestations

The manifestations of HSV infection are dependent on the anatomic site involved, the immune status of the host, and the HSV serotype. Oropharyngeal/orofacial infection predominates after HCT [2], followed by infection of the genital or perianal area [31]. Other sites that are infrequently involved include the esophagus, lung, liver, and central nervous system (CNS), usually in the setting of dissemination.

Oropharyngeal/orofacial infection

The majority (92%) of HSV infections present with oropharyngeal or orofacial lesions, irrespective of the use of antiviral prophylaxis [2,31]. In an observational study by van der Beek et al., the polymerase chain reaction (PCR) methodology was employed to assess oral viral shedding and its correlation with the presence of oral ulcers/mucositis in HCT recipients in the absence of antiviral prophylaxis [32]. Multivariate analysis revealed that the HSV-1 viral load was a positive predictor of ulcerations on the keratinized mucosa (odds ratio 1.35, $p = 0.0005$) but not for ulcerative mucositis. Mucositis following HCT is often confused with HSV infection. Woo et al., demonstrated that HSV does not play a major role in mucositis in HCT recipients receiving acyclovir prophylaxis [33]. Mucositis-related ulceration tends to involve non-keratinized mucosa, in contrast to HSV which affects keratinized mucosa.

Primary infection in the normal host is characterized by painful gingivostomatitis and pharyngitis that are often accompanied by fever and lymphadenitis. This presentation is uncommon in HCT recipients as disease is mostly due to reactivation. Patients may present with a typical vesicular rash located at the vermilion border of the lips, nasolabial fold (Figure 88.1a), or palate that progresses to ulcerative lesions. More serious oral disease may manifest as severe mucositis with painful deep ulcers (Figure 88.1b). In the setting of severe immunosuppression, HSV disease may spread to the esophagus or trachea. Bacterial or fungal (especially *Candida*) superinfection can occur. Pain is a common complaint. Response to treatment is typically slow and may take weeks to resolve.



(a) (b)

Figure 88.1 (a) Vesicular lesions of HSV along the nasolabial fold in an HCT recipient. (b) HSV ulceration of the tongue caused by an acyclovir-resistant strain.

Genital/perianal infection

In the pre-antiviral prophylaxis era, about 6% of HCT recipients developed genital HSV [2]. However, with the use of antiviral prophylaxis, reactivation of genital HSV was noted in 15% of patients [31], possibly reflecting the relatively higher acyclovir resistance of HSV-2 compared with HSV-1.

Primary infection presents with fever, inguinal adenopathy, and vaginal or urethral discharge, and the symptoms do not differ based on the HSV type. However, HSV-2 is associated with more frequent recurrences of genital herpes compared with HSV-1, and may be associated with recurrent aseptic meningitis. As mentioned previously, primary HSV infection is uncommon after HCT, and genital HSV is primarily due to reactivation from the sacral ganglia. It usually presents as patches of vesicular lesions in and around the genital area and may be associated with itching, burning, or pain. Symptoms of urethritis or cystitis may be present. The vesicles typically break down to form shallow, painful ulcers that may coalesce to form large, deep ulcers. Infection can also involve the perianal skin, buttocks, and hips. Inguinal lymphadenopathy can occur. Rectal involvement may also occur and is typically associated with severe pain, tenesmus, and constipation, and may cause rectal bleeding. Acute episodes of genital HSV (both primary and recurrent) can be complicated with acute urinary retention, constipation, and neuropathic pain. This has been attributed to autonomic dysfunction related to infection [34]. The unilateral occurrence of lesions can be confused with varicella zoster virus (VZV) infection. Uncommonly, cytomegalovirus (CMV) infection may lead to ulcerative lesions in the genital/perineal area [35]. The differentiation between these conditions is important for appropriate management.

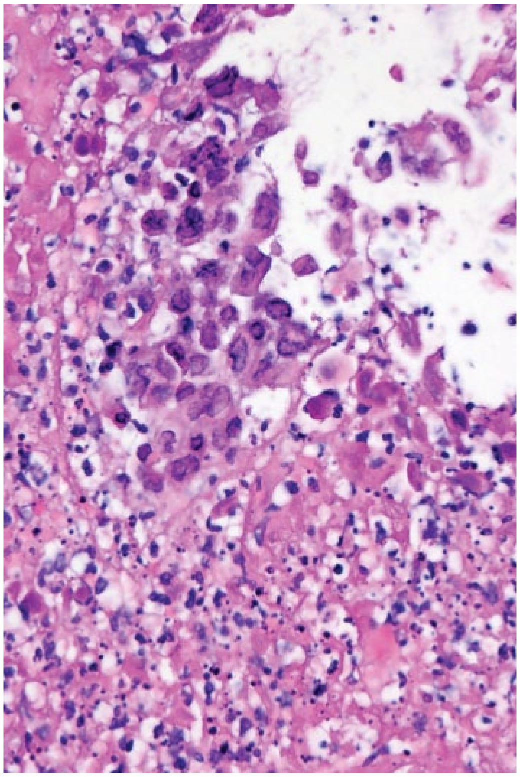


Figure 88.2 Histology of HSV esophagitis: ulceration with cellular changes depicting viral inclusions.

Gastrointestinal infection

This entity has become rather uncommon with the use of antiviral prophylaxis. The most commonly involved site is the esophagus. HSV esophagitis may develop as a consequence of direct extension from the oropharynx or by reactivation of latent HSV from the vagus nerve [36]. The symptoms of HSV esophagitis include persistent nausea and vomiting, dysphagia, and retrosternal pain [37], although acute GVHD, CMV, and *Candida* can cause similar symptoms [38]. Onset can be abrupt but distinguishable from heartburn. HSV causes ulcerative disease and endoscopic examination is necessary to establish diagnosis. McDonald et al. provide a detailed description of the endoscopic findings of HSV esophagitis [37]. The infection progresses through different stages: discrete raised vesicles initially, followed by ulceration, and eventually diffuse mucosal necrosis. However, biopsy of the abnormal area and culture is necessary to make a diagnosis, as clinical symptoms, radiographic studies and morphology seen on endoscopy cannot distinguish HSV infection from other etiologies, especially CMV or VZV (Figure 88.2).

Intestinal HSV infection is extremely uncommon after HCT, and the diagnosis is difficult to establish. In two of three HCT recipients with intestinal HSV infection, diagnosis was made by assessment of surgical specimens obtained at laparotomy [39,40], and one had an endoscopic examination with a colonic biopsy [41]. All developed disease in the first 50 days after HCT and had documented GVHD. Of the two patients who underwent laparotomy, one had ileus, diffuse abdominal pain, ascites, and bleeding [39], and the other had abdominal pain, diarrhea, and bleeding [40]. Both had involvement of the small bowel. Diagnosis was established by histological examination and confirmed as HSV-1 by culture. Both died from uncontrolled hemorrhage despite surgical intervention. The third case had documented genital HSV-2 breakthrough infection 36 days after HCT, and 11 days later developed diarrhea. Endoscopic examination revealed ulcerations in the ileocecal area and biopsy culture grew HSV-2 and CMV. However, the histology was negative for viral inclusions. Full recovery was achieved with antiviral treatment that was confirmed by repeat endoscopic examination with biopsies [41]. It is plausible that the patients with fatal infection probably had disseminated visceral infection, but no discernible site of reactivation was observed by the authors. However, the last case illustrates the potential involvement of the colon in conjunction with genital HSV-2 infection due to reactivation from the sacrococcygeal ganglia rather than disseminated infection.

Hepatitis is fairly rare but causes significant mortality. In one series, eight cases were identified over a 14-year period in an HCT population base of 3000 recipients [42]. HSV-1 and HSV-2 were equally distributed in this group. The most common presentation was fever, abdominal pain, and absence of herpetic skin lesions. The median peak aspartate aminotransferase level was 1565 units/L. In only two cases was the diagnosis considered ante mortem and treatment initiated. All of the cases were fatal. HSV hepatitis represents true dissemination as multiple organ involvement was found in the majority of the cases. In this study, cases from the preprophylaxis era occurred before day 20, whereas those who received prophylaxis did not develop disease until after day 40.

Respiratory infection

It is generally believed that HSV-1 respiratory infection results from an extension of oropharyngeal infection into the tracheobronchial tree. Necrotizing HSV pneumonia develops by extension of herpetic tracheobronchitis (which may be facilitated by the presence of an endotracheal tube), whereas diffuse interstitial

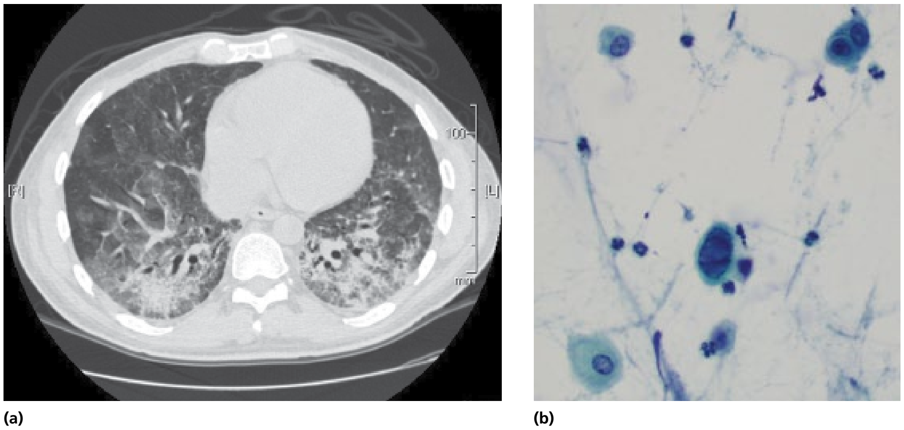

Figure 88.3 (a) HSV pneumonia in an HCT recipient: CT scan image shows mix of ground-glass interstitial infiltrates, nodular changes, and consolidation. (b) BAL fluid cytology from a patient with HSV pneumonia, depicting cellular changes of HSV with typical viral inclusions.

pneumonitis results from hematogenous dissemination [36]. Approximately 6–8% of interstitial pneumonia after HCT is attributed to HSV [43]. Both HSV-1 and HSV-2 can cause pneumonia [43,44]. Clinical presentation includes fever, dry cough, chest pain, dyspnea coupled with hypoxemia, and pulmonary infiltrates on imaging study (Figure 88.3a). Radiographic findings with high-resolution chest tomography (HRCT) scan can be diverse, such as diffuse ground-glass interstitial infiltrates, small centrilobular nodules, and air space consolidation [44]. HSV pneumonia has a high fatality rate (>80%) [43], which does not appear to have changed in the era of antiviral prophylaxis [45]. Diagnostic evaluation involves bronchoscopy with bronchoalveolar lavage (BAL) for viral culture and cytology (Figure 88.3b). Careful assessment needs to be made when attributing pneumonia to HSV based on respiratory cultures, especially in an individual at low risk for HSV pneumonia. This is important as oral shedding (asymptomatic or symptomatic) of HSV is commonly found in HCT patients and can lead to contamination of cultures by the virus.

Central nervous system

HSV encephalitis is a rare complication after HCT. It occurs in the general population with a frequency of 1 in 250,000–500,000 persons per year, and does not appear to be more common in HCT [46]. In the "normal host," the clinical presentation consists of a subacute onset of fever and focal, primarily temporal lobe, neurologic signs and symptoms. In an immunocompromised host, the presentation may be atypical, with a subacute but progressively deteriorating course [47]. However, an HCT recipient was recently described to have presented with classic HSV encephalitis manifesting with anomia, focal findings of temporal lobe encephalitis on magnetic resonance imaging (MRI) of the brain, abnormal electroencephalogram (EEG), and confirmed with positive cerebrospinal fluid (CSF) PCR for HSV [48]. CSF assessments with HSV PCR, MRI, and EEG are diagnostic mainstays. Other herpesviruses should be excluded, such as HHV-6, CMV, and Epstein–Barr virus (EBV).

Other syndromes

HSV-associated erythema multiforme (EM)

EM is a newly described entity in HCT, and considered to be an autoimmune phenomenon. Expression of the HSV DNA polymerase gene in skin lesions is considered to be the hallmark of this condition in the absence of local HSV replicative infection. An interesting observation of erythematous eruptions in the setting of HCT was reported by Burnett et al. [49]. Rash is a frequent event after HCT, and Burnett et al. described a diffuse erythematous rash (maculopapular, bilaterally symmetrical with predilection for acral regions, evolving into plaque-like lesions followed by desquamation) that occurred 3–15 days after HCT in 20 patients. Of the 19 patients with rash, 79% of skin biopsies had expression of HSV DNA polymerase (without molecular evidence of active HSV infection) compared with 75% in herpesvirus-associated EM. Therefore, it was concluded that this syndrome falls into the spectrum of EM. Chronic suppressive treatment with acyclovir is suggested in those with severe EM associated with HSV infection [50]. The therapeutic implication of this finding is unclear, since HCT recipients are usually on a prophylactic antiviral agent, and increasing the dose may not be justifiable in the absence of active infection.

Eye infection

HSV eye infections are uncommon in HCT. They may present with keratitis secondary to reactivation of HSV from the trigeminal ganglia or autoinoculation from a distant site of active HSV infection (such as oral or genital). GVHD of the eye may predispose to HSV infection due to impairment of local defenses or abnormal tear fluid [51]. HSV chorioretinitis is well described in the setting of HIV infection but rare in HCT. Progressive outer retinal necrosis can present with rapidly progressive visual impairment, leading to blindness, and requires an aggressive management approach in consultation with an ophthalmologist. VZV can cause a similar presentation and needs to be ruled out.

Herpetic whitlow

This is an HSV infection of the finger. Clinical manifestations include pain, swelling, erythema, fever, local tenderness, local lymphadenopathy, and the presence of lesions on the affected finger. This condition can result from autoinoculation or contact with bodily secretions (oral or genital) that contain virus. Management entails the use of an antiviral agent. Surgical debridement should be avoided.

Diagnosis

Identification of HSV infection relies upon both clinical suspicion and laboratory confirmation. Serology is of very little use in the post-HCT setting as HSV infection is mostly due to reactivation of latent infection. Its role in HCT candidates is to determine past HSV exposure. Moreover, it has been reported that the risk of HSV reactivation is proportional to the pre-HCT HSV immunoglobulin G (IgG) titer [52]. Glycoprotein G-directed IgG antibody differentiates between HSV-1 and HSV-2 [53].

The presence of characteristic vesicular lesions in clusters on an erythematous base near or around perioral or genital areas can lead to clinical diagnosis. However, this stage is often missed and ulcerative lesions are frequently encountered. Distinguishing oral HSV lesions from mucositis caused by HCT-related conditioning or alternative pathology may be difficult, while genital HSV may present with atypical lesions. In these situations, viral culture and/or PCR for HSV DNA should be obtained from the vesicle or ulcer base. Scraping of the lesion should be considered for rapid diagnosis. The specimen can be examined microscopically after Giemsa (Tzanck preparation), Wright, or Papanicolaou staining to assess for the presence of intranuclear inclusions and/or multinucleated giant cells suggesting herpesvirus infection. However, this does not differentiate HSV from VZV infection, and therefore the preferred test is detection of HSV (and VZV) antigen or DNA detection. The scrapings can be submitted for antigen detection by direct fluorescent antibody (DFA), peroxidase, or enzyme-linked methods. PCR is more sensitive than culture and should be considered when evaluating for suspected HSV infection [54]. In the instance of a respiratory tract specimen, BAL fluid should be examined for HSV-related cellular changes when HSV pneumonia is suspected.

The gold standard of diagnosis is virus isolation. The positive culture will also provide the opportunity to test for antiviral resistance. Culture for HSV is recommended when acyclovir resistance is suspected. Clinical specimens submitted for culture should be transported on ice and immediately inoculated into a cell culture system. A cytopathic effect may develop within 24–48 hours, but definitive identification may take from 48 to 96 hours. A more rapid culture technique is the spin-amplified culture, or shell vial culture, with subsequent staining for specific HSV antigen. The shell vial culture result can be reported in less than 24 hours. PCR is the method of choice for the diagnosis of CNS HSV infection [55].

Tissue biopsy is necessary to confirm the diagnosis of visceral HSV infection. The tissue should be submitted for culture and histologic examination. The demonstration of tissue pathology is important in differentiating between disease, shedding of virus, and contamination. Viral inclusions suggestive of HSV infection are often absent in necrotic cells seen on tissue sections [37] and, if detected, difficult to differentiate from CMV or VZV. The use of techniques such as immunostaining or *in situ* hybridization can help in confirming infection [37,39,40]. This approach may potentially expedite a diagnosis while waiting for viral culture.

Management of HSV infection in HCT

Acyclovir remains the drug of choice for treatment of HSV infection since its introduction into clinical practice in the early 1980s. Other antiviral agents in clinical use with activity against HSV are foscarnet and cidofovir (Table 88.1). The approaches to the management of HSV in HCT include (1) treatment of reactivated infection and (2) prevention with antiviral prophylaxis. These approaches have reduced the burden of disease. However, antiviral resistance to acyclovir and other agents is an emerging issue and poses therapeutic challenges [28,32,45,56–62].

Table 88.1 Antiviral prophylaxis and treatment for HSV infection

Prophylaxis
Acyclovir 250 mg/m^2 or 5 mg/kg intravenously every 12 hours, or
Acyclovir 400–800 mg orally every 12 hours, or
Valacyclovir 500–1000 mg orally every 12 hours
Treatment
Mucocutaneous HSV infection
Acyclovir 250 mg/m^2 or 5 mg/kg intravenously every 8 hours, or
Acyclovir 400 mg orally 5 times per day, or
Valacyclovir 500–1000 mg orally every 12 hours, or
Famciclovir 500 mg orally every 12 hours
Visceral/disseminated/CNS disease
Acyclovir 500 mg/m^2 or 10 mg/kg intravenously every 8 hours
Acyclovir-resistant HSV infection
Foscarnet 40–60 mg/kg intravenously every 8 hours
Acyclovir/foscarnet-resistant HSV
Cidofovir 5 mg/kg intravenously once weekly x 2, then every 2 weeks, or
Cidofovir 1 mg/kg intravenously once every other day or three times per week
Other considerations
In the setting of mucocutaneous infection that is severe, slowly resolving or intolerable side effects of systemic antiviral treatment, may consider topical 5% cidofovir gel

Acyclovir is a nucleoside analog and requires phosphorylation by viral thymidine kinase (TK) and cellular enzymes to result in the formation of acyclovir triphosphate. Viral DNA polymerase is competitively inhibited by acyclovir triphosphate, leading to its antiviral effect [63]. It is usually given intravenously but can be given orally if the patient is capable of taking and absorbing the oral formulation. Intravenous acyclovir was compared with placebo in one of the early double-blind studies [64], and shortened the time to resolution of pain (10 versus 16 days), crusting of lesions (7 versus 14 days), healing (14 versus 28 days), and duration of culture positivity (3 versus 17 days). This study is the basis for the current standard of therapy: acyclovir 250 mg/m^2 or 5 mg/kg intravenously every 8 hours for at least 7 days. Oral acyclovir therapy for mucocutaneous HSV given as 400mg five times per day for 10 days demonstrated similar benefit [65], although the oral route should be considered only if the gastrointestinal absorptive capacity is considered to be adequate. In immunocompromised HCT patients, antiviral treatment should be continued until mucocutaneous lesions have completely resolved. Valacyclovir (valyl ester of acyclovir), and famciclovir (prodrug of penciclovir) result in higher serum levels and can be used, although they have not been extensively studied in HCT patients. If the patient has severe mucocutaneous, visceral, disseminated, or CNS disease, acyclovir 10 mg/kg every 8 hours is recommended. Each dose should be infused slowly over 1 hour and adequate hydration maintained to avoid renal dysfunction, which can result from crystallization of the drug.

Acyclovir resistance should be suspected in patients who worsen despite adequate therapy with acyclovir, individuals with multiple episodes of recurrent HSV, and the highly immunocompromised (such as GVHD grade >2, haploidentical HCT) [28,57]. Foscarnet is the drug of choice for suspected or proven acyclovir-resistant HSV infection. It is a trisodium salt of phosphonoformic acid and inhibits viral DNA polymerase without requiring TK activity and therefore is active against TK-deficient HSV. It is dosed at 40 mg/kg every 8 hours, and for severe disease or visceral involvement, 60 mg/kg every 8 hours is recommended. The major and limiting toxicity of foscarnet is nephrotoxicity, making it essential to avoid other nephrotoxic agents and maintain hydration. It also causes electrolyte imbalance, mainly hypocalcemia, hypokalemia, and hypophosphatemia. All of these toxicities make it difficult to use foscarnet in the HCT setting. Foscarnet-resistant strains have been reported [56], and linked to a mutation in viral DNA polymerase, which affects binding of the drug to the active site [63]. In such cases, cidofovir has shown some benefit and is recommended at 5 mg/kg intravenously once per week for 2 weeks, and then once every 2 weeks [66]. It acts by inhibiting viral DNA polymerase. The major limiting factor is nephrotoxicity, attributed to accumulation of the drug in the renal cortex. Probenecid is given with cidofovir to reduce its nephrotoxicity. A dosing regimen of cidofovir 1 mg/kg three times weekly regimen has been described in treating adenovirus infection [67]. No dose-limiting nephrotoxicity was observed and all patients resolved infection. Hence this dosing regimen has been used for acyclovir- and foscarnet-resistant HSV infections in HCT by the authors. However, no data are available for HSV infections. Few reports documenting the success of topical cidofovir in clearing acyclovir/foscarnet-resistant mucocutaneous infection in HCT have been published [68,69]. Cidofovir-resistant HSV strains have been described in HCT recipients [61,62]. Fortunately, these isolates remained sensitive to both acyclovir and foscarnet.

Topical trifluridine, idoxuridine, and vidarabine are used mainly in the context of HSV keratitis. New drugs in development include CMX001 and helicase–primase inhibitors [70]. CMX001 is an orally administered lipid conjugate of cidofovir, with excellent activity against HSV-1 and numerous other DNA viruses (e.g. CMV, adenovirus, smallpox). Helicase–primase inhibitors (ASP2151 – recently compared with valacyclovir for the treatment of genital herpes) inhibit viral DNA synthesis by interfering with the helicase–primase of HSV [71]. However, none of these drugs are approved for clinical use at present.

Prophylaxis

Acyclovir prophylaxis should be offered to all seropositive allogeneic recipients to prevent HSV reactivation during the early post-HCT period, as recommended by the Centers for Disease Control and Prevention (CDC), the Infectious Diseases Society of America (IDSA), the American Society for Blood and Marrow Transplantation (ASBMT), and others [72,73]. Despite the official recommendations and the fact that most HCT centers use HSV prophylaxis, the decision regarding the use of universal prophylaxis is not without controversy. Significant variability in practice exists between transplant centers [4]. The recommended regimen is either acyclovir 200 mg orally three times per day or 250 mg/m^2 intravenously every 12 hours. Valacyclovir is a recommended alternative. Antiviral prophylaxis should commence at the beginning of conditioning therapy and be continued until engraftment or resolution of mucositis, that is, approximately 30 days after allogeneic HCT. The duration of prophylaxis can be extended beyond 30 days for those who develop GVHD or with "frequent HSV reactivation." Viral shedding and reactivation of HSV have decreased dramatically with prophylaxis, yet disease occurs when prophylaxis is stopped [3,5]. The frequency of reactivation and severity of disease are decreased when prophylaxis is extended beyond 30 days [74,75]. Delayed immunologic reactivity to HSV antigens and specific immune reconstitution have been observed with antiviral prophylaxis [5]. Whether this delay is detrimental or has benefit is unknown. Another argument for prophylaxis is the observation that resistant virus emerges on treatment but rarely with prophylaxis [76,77].

The efficacy of long-term antiviral prophylaxis has been evaluated [77,78]. Three cohorts of HSV and VZV seropositive patients received prophylaxis for either 1 month, 1 year, or longer than 1 year after HCT. The 2-year probability for developing HSV disease was 31.6, 3.9, and 0%, respectively. Hence long-term prophylaxis resulted in less disease/reactivation, and also prevented the emergence of drug-resistant HSV. Higher than recommended prophylactic doses were used (acyclovir 800 mg orally twice daily or valacyclovir 500 mg twice daily after engraftment) and no hematologic toxicity was noted. It is plausible that higher doses of antiviral agent used translated into increased serum levels, thereby preventing the emergence of resistance. Long-term (at least 1 year) prophylaxis is considered to be the standard of care for VZV prevention in HCT at most transplant centers. Hence the burden of recurrent HSV disease and antiviral resistance should decrease. There are reports of earlier engraftment in patients receiving acyclovir prophylaxis [5], but this has not been confirmed by others [52,79].

The ultimate preventive measure is the development of a vaccine that will prevent primary HSV infection in the general population, which has been a challenge [80]. Preferably, it would be a killed, subunit, replication-defective viral or naked DNA vaccine, as a live vaccine would have the unknown potential of reactivating during HCT. The most recent vaccine was not efficacious in preventing genital herpes [80], and there will be no effective vaccine in the near future. Also, it is unlikely that a vaccine will benefit those who are already seropositive, especially in the prevention of HSV reactivation in the profoundly immunocompromised seropositive population of HCT recipients.

Conclusion

Since the inception of acyclovir prophylaxis, the incidence of HSV reactivation and disease has decreased dramatically during the early period of HCT. However, prophylaxis as now administered (until engraftment or approximately 30 days) under current recommendations and has resulted in delay of HSV-specific immune reconstitution, and reactivation now occurs during the later period of HCT. However, severe, visceral, and disseminated HSV infection still occurs and demands rapid and specific diagnosis in order to initiate effective therapy. Although resistant virus is less likely to occur under prophylactic conditions, it remains a significant problem in treating patients with HSV infection after HCT. A possible solution to the late reactivation after early cessation of prophylaxis and the problem of emergence of acyclovir-resistant HSV may be to extend the duration of HSV prophylaxis (in addition to using higher doses than currently recommended). At the same time, this would protect the HCT recipient against VZV reactivation, which may be an even more devastating infection. However, further examination of this approach will have to be undertaken before a recommendation for longer duration of prophylaxis can be made.

CHAPTER 89

Varicella Zoster Virus Infections

Dora Y. Ho and Ann M. Arvin
Stanford University School of Medicine, Stanford, CA, USA

Introduction

Varicella zoster virus (VZV), like other pathogens of the herpesvirus family, can cause severe infections in hematopoietic cell transplant (HCT) recipients [1,2]. As in other immunodeficient patients, serious VZV disease after transplantation is related to the compromise of T-lymphocyte function [3,4]. VZV infections are encountered in HCT patients who are experiencing their initial contact with the virus or who have recurrent disease due to the reactivation of latent virus. Primary VZV infection is manifest clinically as varicella or "chicken pox," in which the exposure of a susceptible individual, who has not had previous VZV infection, to the virus results in systemic symptoms of fever and malaise, and a characteristic vesicular rash. After primary infection, VZV establishes latency in cells of the dorsal root ganglia. Serum immunoglobulin G (IgG) antibodies to VZV provide evidence of a past primary infection and indicate that the individual is latently infected with the virus. The reactivation of endogenous latent VZV usually causes herpes zoster, in which the vesicular eruption appears in a localized, dermatomal distribution. Recurrent VZV infection also presents as atypical, non-localized herpes zoster in HCT recipients that cannot be distinguished from varicella by its clinical manifestations. Both primary and recurrent infections of VZV can cause significant morbidity and, in some cases, even mortality in HCT recipients.

In addition to describing the clinical patterns of VZV infection after HCT, significant progress has been made towards understanding viral pathogenesis and the host response to VZV among HCT recipients. Fortunately, most disease caused by either primary or recurrent VZV infection, when recognized promptly, can now be treated effectively with antiviral therapy. Although live attenuated VZV vaccines are available for the prevention of varicella in the pediatric population and zoster in the elderly population, these vaccines are not recommended for use in immunocompromised patients. Instead, an experimental inactivated varicella vaccine has been tested in HCT recipients. Prophylactic approaches using antiviral drugs have also been evaluated.

The virus

VZV is a member of the alphaherpesvirus subgroup of the herpesvirus genus. It is an enveloped virus that has a double-stranded DNA genome surrounded by an icosahedral capsid [5]. The VZV genome contains approximately 125,000 base pairs, arranged as long unique and short unique segments, each of which contains terminal repeat sequences. The VZV genome has coding regions for at least 70 distinct genes. Information about most of the VZV gene products is limited, but VZV proteins regulate viral gene transcription during replication and form the viral capsid, tegument, and virion envelope structures. Probable functions for some VZV proteins have been demonstrated by making targeted mutations in the viral genome and assessing the consequences; other gene functions have been deduced from homologies with herpes simplex virus, type 1 (HSV-1), which is the prototype of the alphaherpesvirus subgroup. Like HSV, replication of VZV usually involves synthesis and activation of a viral thymidine kinase which makes the virus susceptible to inhibition by the antiviral agent acyclovir and related drugs. However, since the thymidine kinase is not required for VZV replication, mutant strains that do not express this antiviral target can be selected by exposure to the drug and may cause infection similar to the wild-type virus. The viral glycoproteins gB, gC, gE, gH, and gI and also viral proteins with structural and regulatory functions, including the IE4, IE62, and IE63 proteins, are known to be targets of the host response following VZV infection. VZV is spread as cell-free virus to susceptible hosts, but is transmitted by cell-to-cell spread in the infected host. The VZV glycoproteins gB, gE, gI, and gH are important for cell-to-cell spread [6–11]. Other virulence factors have been identified by evaluating VZV mutants in human xenografts using the severe combined immunodeficient (SCID) mouse model of VZV pathogenesis [12].

Epidemiology

Primary VZV infection

Primary VZV infection, or varicella, is much less common than disease caused by VZV reactivation during the first year after HCT, accounting for only about 5% of VZV infections in this population. The lower incidence of varicella is due to the fact that more than 85% of individuals in the United States have had primary VZV infection by 8 years of age as a result of the annual varicella epidemics that occur in that and other temperate regions of the world. Nevertheless, if an HCT recipient has never had VZV infection before, the attack rate for varicella after close exposure to an index case will reflect the risk of transmission to any susceptible individual, defined as an individual who has not been infected previously. Attack rates range from about 30% with classroom exposure to 90% with household contact. Direct contact with

lesions is not required since, in contrast to other herpesviruses, VZV is transmissible by the respiratory route. The incidence of primary VZV infection is higher in pediatric HCT recipients than adults and, as expected, the risk correlates inversely with the age of the child. In one series, 10 of 54 children (18%) with VZV infections after HCT had primary VZV infection demonstrated serologically [5]. Although 25 adult patients presented with a disseminated cutaneous VZV exanthem, only two patients had serologic evidence of primary VZV infection [1]. Although the possibility of reinfection cannot be eliminated in some cases, the epidemiologic evidence suggests that patients who have been infected previously are usually protected against infection following a new VZV exposure, presumably because VZV IgG titers are maintained despite immunosuppressive disease or therapies. The addition of the varicella vaccine to the routine childhood immunization schedule has reduced the extent of the annual epidemics, making it less likely that HCT recipients who have no pre-existing immunity to VZV will be exposed to varicella, and more likely that pediatric HCT recipients will have vaccine-induced immunity to VZV [13,14].

Recurrent VZV infection

The reported incidence of recurrent VZV infection after HCT ranges from 16 to 63% [1,15–31] (Table 89.1). Cord blood transplant recipients have the highest risk of VZV reactivation, with an incidence of up to 80% reported [26,29]. The incidence of recurrent VZV infection after HCT is higher than that observed among solid organ transplant recipients, which is about 7%, but it is comparable to rates of VZV reactivation in patients with Hodgkin disease receiving combined modality therapy. For purposes of comparison, the estimated annual incidence of herpes zoster in adults without underlying disease is 0.5% [22].

The reactivation of herpesviruses follows a predictable temporal pattern after HCT [2]. HSV-1 causes clinically apparent disease at about 2–3 weeks and cytomegalovirus (CMV) disease usually occurs during the second to third months after transplantation. Epstein–Barr virus (EBV) may also reactivate in the third month whereas VZV recurrences present at a median of 5 months after HCT. In general, the risk of recurrent VZV infection is highest between 2 and 10 months after transplantation, although cases have been reported within the first week and continue to occur after the first year (Figure 89.1). Locksley et al. found that 80% of patients who developed VZV infection following HCT had disease within 9 months [1]. When options for antiviral therapy were limited, 21% of these patients had visceral dissemination of the virus and 12% died from complications of recurrent VZV. In a review of 100 consecutive adult patients who received allogeneic HCT between 1992 and 1997, 41% developed VZV reactivation at a median of 227 days (range 45–346 days) [22]. Of these episodes, 12% occurred in the first 100 days; the attack rate was 59% among patients who survived for at least 2 years. In another retrospective analysis of VZV infection after HCT in children [24], 33 (30%) of the total 109 children who were transplanted during a 7-year period developed post-transplant VZV infection, including six cases of varicella and 27 cases of zoster. Twenty-four of these 33 (73%) children had VZV infection within

1 year following HCT. The cumulative incidences of post-transplant VZV infection at 1 and 5 years were 26 and 45%, respectively.

Factors that are associated with higher rates of VZV reactivation following HCT include genotypic non-identity for human leukocyte antigen (HLA) between donor and recipient, and acute or chronic graft-versus-host disease (GVHD), which are linked variables [23]. In one series, 64% of patients whose donor was HLA non-identical had herpes zoster compared with 44% of HCT recipients with matched donors and no GVHD. The risk of late VZV infection was increased fourfold (Table 89.2) [16]. In a second series, patients with limited chronic GVHD had a lower incidence of VZV reactivation than those with extensive chronic GVHD [22]. The presence of non-specific suppressor cells associated with chronic GVHD correlated with a higher risk of recurrent VZV (Table 89.2) [16]. A CD4 T-cell count <200 cells/μL and a CD8 T-cell count <800 cells/μL at 30 days after transplantation correlated with an increased risk of zoster within the first year [25]. The cumulative evidence indicates that patients undergoing allogeneic or autologous HCT have about the same overall risk of recurrent VZV disease although, as noted, cord blood HCT seems to pose the highest risk for VZV reactivation [26] (Table 89.1). In one study, 28% of autologous transplant patients developed recurrent VZV infection [19]. The initial manifestation of recurrence was localized disease in 77% of these patients while 23% had atypical non-localized zoster, which is comparable to the distribution of these clinical syndromes among allogeneic HCT recipients. Some 32% of patients who received an autologous HCT for Hodgkin lymphoma had VZV infection [20], which is consistent with experience in Hodgkin and non-Hodgkin lymphoma patients [32]. The somewhat higher incidence of zoster in lymphoma patients may account for the fact that patients who receive autologous HCT have rates of VZV reactivation that are similar to those in allogeneic HCT recipients even though GVHD is less common. Morbidity and mortality caused by VZV infection after autologous HCT cannot be compared with the original analyses of VZV-related disease after allogeneic HCT because antiviral therapy was available when the studies of autologous HCT patients were carried out. In the series of Schuchter et al., 15% of autologous HCT recipients had cutaneous dissemination, 5% had visceral dissemination, and 25% had morbidity, including postherpetic neuralgia (PHN) and neurologic dysfunction [19]. In a more recent series of pediatric HCT patients, 61 of 201 (35%) allogeneic HCT recipients compared with 10 of 109 (9%) autologous HCT recipients developed zoster. Risk factors for the development of zoster included age >10 years, allogeneic HCT, and total body irradiation in allogeneic recipients [33].

The underlying disease that provided the indication for HCT probably does not influence VZV reactivation. However, a history of symptomatic herpes zoster before marrow transplantation was associated with a higher risk of early post-transplant VZV disease among patients with Hodgkin disease undergoing autologous HCT [20]. VZV reactivation has not been found to predict relapse of the underlying disease in HCT recipients.

Reinfection with VZV

Natural immunity following varicella usually protects against systemic reinfection. For this reason, symptomatic reinfection with VZV is very rare among immunocompetent individuals. Surveillance of 9947 cases of varicella indicated that 4.5–13.5% of children presenting with varicella had a documented previous episode of varicella, suggesting that clinical reinfection may be more common than previously thought [34]. However, most of these cases of varicella were not laboratory confirmed and other childhood viral illness can also present with vesicular rashes. Furthermore, a study in adults showed that a history of previous varicella infection in adults was not reliable based on absence of VZV IgG antibodies in preillness serum specimens [35]. Reinfection probably occurs occasionally among severely immunocompromised patients who have had primary VZV infection previously [36]. However, this hypothesis is difficult to confirm because the distinction between atypical non-localized herpes zoster (which is much more common in immunocompromised patients) and reinfection requires a comparison of the VZV isolates causing the initial infection and the new episode by DNA sequence analysis. Based on clinical criteria only, children with leukemia have been reported to have second episodes of varicella following close

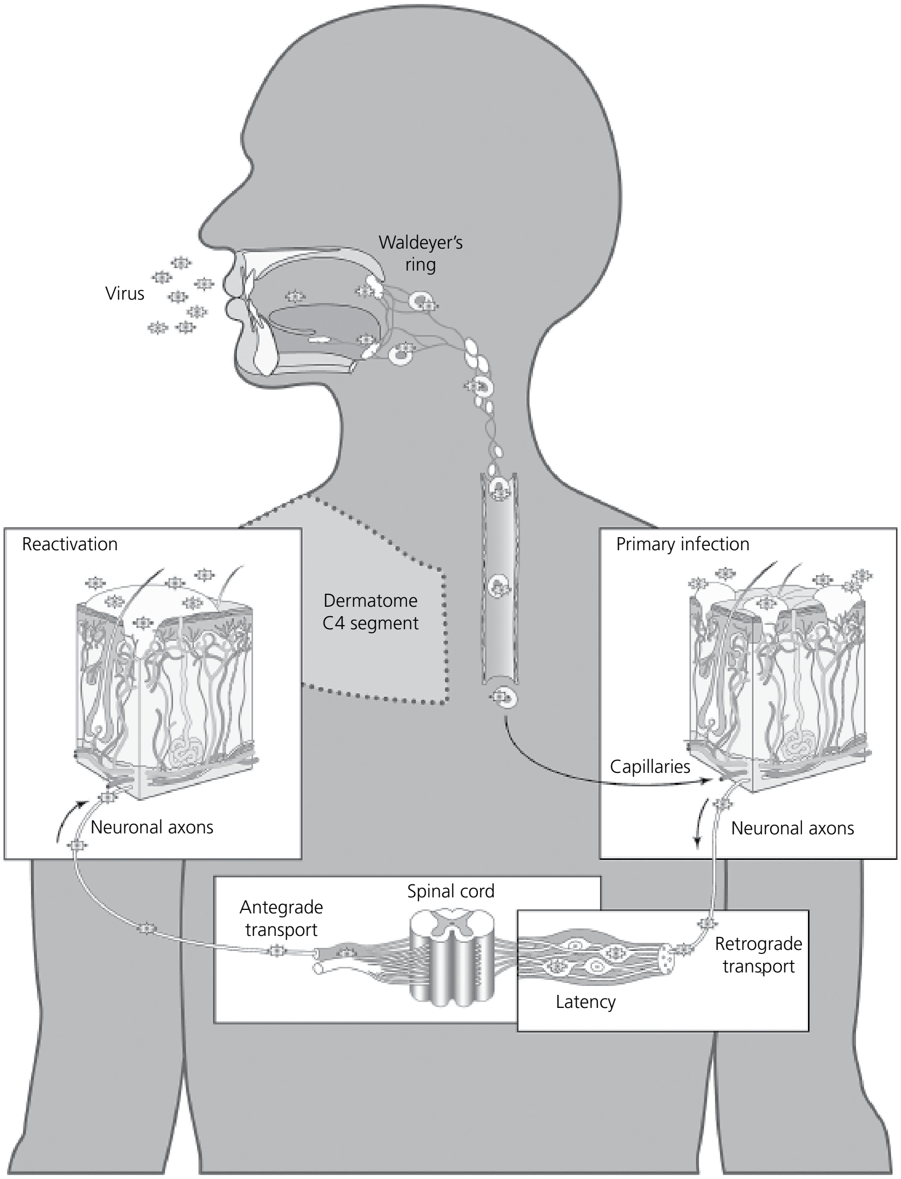

Figure 89.2 The pathogenesis of VZV infection in the human host. VZV infection is acquired by inoculation of mucosal epithelial cells. Since VZV is a T-cell tropic virus, infection of T cells in lymphoid tissues of Waldeyer's ring can amplify the infection and infected T cells can then transport VZV to the skin via a cell-associated viremia. Infection of skin produces the vesicular rash associated with chickenpox. During skin infection, VZ virions gain access to the sensory nerve cell body by retrograde axonal transport from fine nerve endings or via cell-associated viremia, to establish a lifelong latent infection within the sensory ganglia. Herpes zoster results from reactivation of latent VZV. During reactivation, VZ virions gain access to skin via anterograde transport along neuronal axons, causing a localized dermatomal rash. In immunocompromised patients, reactivation may result in T-cell infection and dissemination, with or without a dermatomal rash.

contact despite a past history of varicella and serologic evidence of pre-existing immunity. Nevertheless, anecdotal experience suggests that exposure of HCT patients who have had past primary VZV infection rarely causes any clinically apparent signs of reinfection [2].

Mechanisms of pathogenesis and viral immune evasion

Primary VZV infection

Events during the 10–21-day incubation period of primary VZV infection have been difficult to document with laboratory methods. The epidemiologic evidence suggests that infection is initiated by the inoculation of respiratory mucosal sites (Figure 89.2) [5]. Infectious virus is then presumed to be transported to regional lymphoid tissue, possibly undergoing a phase of local replication at these sites. VZV causes a cell-associated viremia, which appears to target T-lymphocytes in particular, although other cells of the immune system, such as dendritic cells, can become infected. Tonsillar T cells are highly permissive for VZV infection, suggesting that VZV could be transferred efficiently from respiratory epithelial cells into these local T-cell-rich tissues as a first stage of spread within the naïve host [37]. Cell-associated viremia has been demonstrated late in the incubation period, just before and after the appearance of

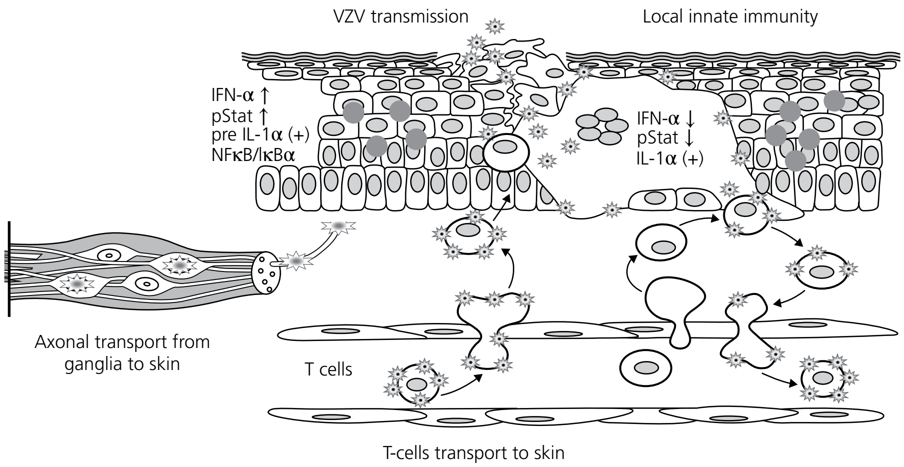

Figure 89.3 The pathogenesis of primary and recurrent VZV infection is modulated by innate immune responses of cutaneous epithelial cells. This diagram depicts new concepts about events in the pathogenesis of VZV infection of skin. During primary VZV infection, T cells within the tonsil lymphoid tissues become infected by VZV. Infected T cells transport the virus to the skin shortly thereafter, exiting through capillary endothelium by the usual mechanisms for trafficking of migratory T cells. The infected T cells then release infectious VZV at skin sites of replication. The remainder of the 10–21-day incubation period is the interval required for VZV to overcome the innate IFN-α and other antiviral responses in enough epidermal cells to create the typical vesicular lesions containing VZV at the skin surface. Signaling of innate responses, such as signal transducers and activators of transcription-1 (Stat-1), IL-1α and nuclear factor-kappa B (NFκB), in adjacent skin cells prevents a rapid, uncontrolled cell–cell spread of VZV. When uninfected T cells that are trafficking through skin in normal immune surveillance encounter early-stage cutaneous lesions, they may become infected and amplify viremia. When VZV reactivates from latency in sensory neurons, it is delivered to the skin by axonal transport. VZV replication in the involved dermatome encounters innate barriers as the initial host response, followed by the appearance of VZV-specific T cells that clear active infection. If these responses are delayed, the virus may enter migrating T cells to cause disseminated VZV infection.

varicella skin lesions. VZV was isolated by viral culture from 24% of samples of peripheral blood mononuclear cells (PBMCs) taken within 24 hours after the onset of rash [38]. Cell-associated VZV viremia was detected by in situ hybridization with a probe for VZV DNA, which showed viral DNA in lymphocytic cells, and by polymerase chain reaction (PCR) testing for viral DNA in PBMC specimens from otherwise healthy subjects tested immediately after the appearance of skin lesions [39]. VZV infection of tonsillar T-lymphocytes was enhanced in activated, memory CD4 T-lymphocytes that expressed skin homing markers, which suggests that cell-associated viremia may be particularly associated with infection of this subpopulation of T-lymphocytes [37]. When the cutaneous exanthem develops, VZV replication in epithelial cells may amplify viremia by transfer of infectious virus into migrating T-lymphocyte populations, leading to secondary 'crops' of skin lesions. These observations about the pathogenesis of primary VZV infection suggest that the efficiency with which cell-associated viremia and replication at skin sites is terminated, either by the host response or by antiviral therapy, is likely to influence the extent of the cutaneous exanthem and the risk of visceral dissemination (Figure 89.3).

The study of VZV pathogenesis in animal models has been hampered by the restricted replication of the virus in non-human species. Mice that have inherited SCID can be used to support grafts of human tissues that differentiate to contain the usual human cell populations. These animals, which are referred to as SCID-hu mice, provide a unique opportunity to examine VZV–cell interactions in intact human tissues independently of the effects of the host immune response on viral replication [40,41] (Figure 89.4; reviewed in [11,12,42,43]). Conditions in the model are similar to those in the period immediately after HCT, since VZV-specific immunity is absent. Experiments in the SCID-hu mouse model demonstrated that VZV infects CD4$^+$ and CD8$^+$ human T-lymphocytes, proving that VZV shares pathogenic mechanisms that are characteristic of both the lymphotropic and the neurotropic herpesviruses [42]. The tropism of VZV for human T cells and its infectivity for skin are both essential elements of its pathogenicity in human disease, but comparative analyses of VZV strains demonstrate that these tropisms are mediated by different virulence determinants. For example, the VZV strain used to make the live attenuated varicella vaccine, the vaccine Oka strain, was indistinguishable from low-passage VZV in its infectivity for CD4$^+$ and CD8$^+$ T cells whereas its pathogenic potential in human skin was reduced substantially compared with the parent Oka strain, as assessed by the extent of the cutaneous lesions, viral protein synthesis, infectious virus yields, and release of infectious virus. Transfer of VZV from infected T cells into skin, followed by the appearance of VZV skin lesions, was demonstrated in the SCID-hu model [44]. These experiments also revealed the substantial upregulation of interferon-α (IFN-α) production by epidermal cells adjacent to VZV-infected cells and blocking experiments with IFN-α/β receptor antibodies showed the biological importance of these responses. Investigations of VZV and HSV-1 replication in the SCID-hu model also revealed significant differences in cell tropisms that correlate with clinical observations about their pathologic effects in intact and immunocompromised individuals. In SCID-hu mice, VZV caused extensive necrosis in deeper dermal layers of skin implants, but HSV-1 was confined to the epidermis. In contrast to VZV, HSV-1 was not infectious for human CD4$^+$ or CD8$^+$ T -cells, which is consistent with the clinical differences, since primary HSV infection is not associated with viremia in the intact host. HCT recipients and other immunocompromised patients are also susceptible to cell-associated viremia when VZV reactivates, whereas HSV viremia is a rare occurrence during recurrent HSV infection even with intensive immunosuppression.

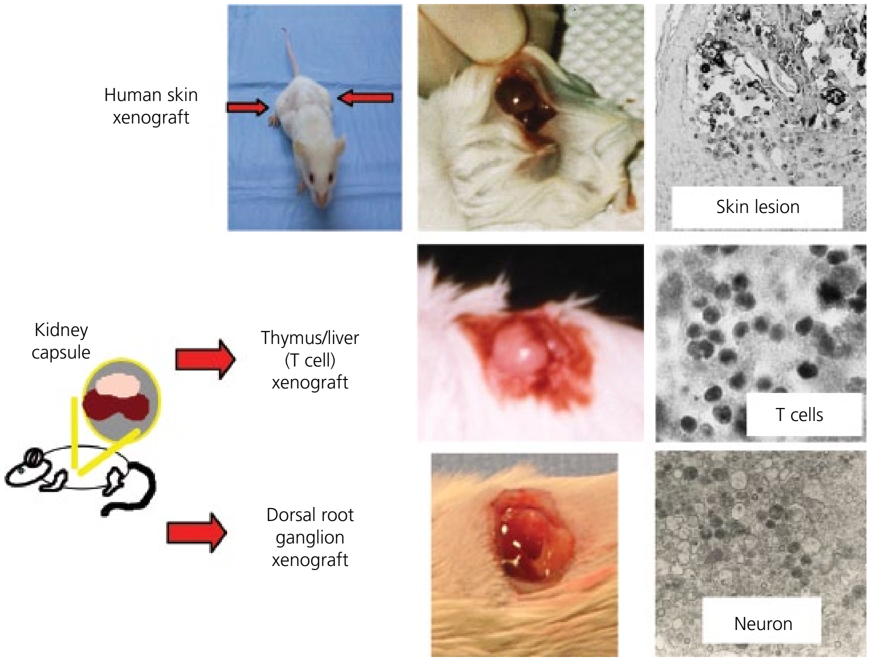

Figure 89.4 Modeling varicella zoster virus (VZV) pathogenesis in human tissue xenografts in vivo. Human tissue xenografts are maintained in mice with severe combined immunodeficiency. VZV infection of cells within their tissue microenvironments can be evaluated in mice with skin, T-cell (thymus/liver) or dorsal root ganglia xenografts. (For a color version of this figure, please see the color plate section.)

Recurrent VZV infection

The hypothesis that VZV becomes latent in sensory ganglia following primary infection and that herpes zoster is caused by its reactivation from latency was proved by using restriction enzyme analysis to demonstrate that a single VZV strain caused both varicella and a subsequent episode of herpes zoster in a child with Wiskott–Aldrich syndrome [45]. During the primary attack, VZV is postulated to pass centripetally from the skin to the corresponding ganglia; hematologic seeding of the ganglia secondary to cell-associated viremia is also likely. Once in the ganglia, VZV establishes latency, apparently without viral replication and without causing cell damage. In contrast to HSV, infectious VZV has not been recovered from ganglion tissue by explant culture or co-cultivation techniques. However, the presence of VZV nucleic acid sequences has been documented in human ganglia taken at autopsy from individuals with no evidence of recent VZV infection [5,46–53]. Multiple VZV RNA sequences have been detected by in situ hybridization and PCR, in contrast to HSV in which only limited gene transcription has been identified in latently infected neurons. Transcription of VZV genes corresponding to ORF4, 18, 21, 29, 40, 62, 63, and 66 have been reported in human dorsal root ganglia (DRGs) from autopsies, although observations about specific VZV genes have varied between studies [52,54,55]. ORF63 transcripts are the most abundant and the most commonly found [54]. Latent infection appears to be more common in the trigeminal ganglion than in any of the thoracic ganglia [50]. In addition to gene transcription, expression of VZV proteins in the cytoplasm of neurons has been described in autopsy specimens from adult subjects without zoster [48,55,56]. However, these observations of VZV protein expression during latency were not substantiated when antibody reagents were used that did not contain murine or rabbit endogenous antibodies to the human blood group A determinant [57]. Blood group A antigen expressed in human neurons resulted in non-specific reactivity. The extensive analysis by Mahalingam et al. identified very few IE63-positive neurons in only a few subjects [55], as was confirmed by Zerboni et al., indicating that VZV transcripts are translated occasionally, perhaps during abortive replication [58]. Basic questions about viral and host mechanisms involved in VZV neuropathogenesis and persistence in human sensory ganglion cells remain unanswered.

Investigations using molecular probes for VZV DNA sequences indicate that the virus persists in neurons [5,49,53]. The study of VZV neuropathogenesis has been facilitated by engrafting human DRGs under the kidney capsules of SCID mice [59]. DRG xenografts contained neurons and satellite cells within a typical DRG architecture. An initial phase of viral replication was characterized by infection of both neurons and satellite cells, inducing fusion of these cell subpopulations [11,60]. This acute process was followed within 4–8 weeks by a transition to VZV latency, characterized by the absence of infectious virus release, the cessation of virion assembly, and a reduction in VZV genome copies. Furthermore, VZV-infected T cells transferred virus from the circulation into DRG, suggesting that VZV lymphotropism facilitates its neurotropism.

The maintenance of VZV latency, as defined by the absence of symptomatic VZV reactivation, is also influenced directly by the host response to VZV, as is evident from the high incidence of VZV reactivation after HCT when VZV immunity is impaired. Although HSV reactivation causes little or no damage to ganglion cells, VZV reactivation is associated with extensive viral replication in the affected ganglia, producing pathologic changes including necrosis, inflammation, and destruction of neural cell bodies.

In contrast to HSV, CMV, and EBV, which can be recovered from asymptomatic patients by viral culture methods, technical problems have interfered with the detection of subclinical VZV reactivation. Episodes of subclinical VZV reactivation, consisting of cell-associated viremia in HCT recipients detected by VZV PCR, were documented in 19% of patients tested at a mean of 94 days after transplantation [61]. Disseminated VZV infection has been diagnosed at autopsy in HCT patients who had no cutaneous lesions [1,62,63]. However, testing PBMCs with the VZV PCR assay provided the first virologic evidence that these severely immunocompromised patients can experience VZV reactivation in the absence of clinically apparent cutaneous infection and resolve the infection without developing signs of visceral dissemination. Herpes zoster, like recurrent HSV, has been attributed to the spread of the reactivated virus along neural pathways from the site of latency in DRGs. Some immunodeficient patients with localized herpes zoster develop VZV viremia, presumably because T-lymphocytes become infected at the site of local cutaneous replication. Subclinical, cell-associated viremia in HCT patients without cutaneous disease suggests that the virus may also be taken up directly by circulating lymphocytes at the neuronal site of viral reactivation. This mechanism for causing viremia could account for the clinical observation of atypical, generalized herpes zoster in some HCT recipients. Since the activation of T-lymphocytes makes this cell population more permissive for VZV infection in vitro [37], cell-associated VZV viremia in HCT patients may be potentiated by the characteristic persistence of activated T-lymphocytes in circulation for a prolonged period after transplant [64].

Viral immune evasion

Like many viruses, VZV has mechanisms to inhibit recognition by the host immune system. We have found that VZV causes a significant reduction of the cell surface expression of MHC class I protein on infected fibroblasts and on infected T cells, as demonstrated in the SCID-hu model [65]. Although their synthesis was not affected, MHC class I molecules were retained in the Golgi in VZV-infected cells. This effect may enable the virus to evade $CD8^+$ T-cell immune recognition during VZV pathogenesis, including the critical phase of T-lymphocyte-associated viremia. In related experiments, we showed that VZV has the capacity to block the upregulation of MHC class II protein that is usually induced when cells are exposed to IFN-γ[66]. Induction of MHC class II expression is required for recognition of virus-infected cells by antiviral CD4 T cells. When skin biopsies of varicella lesions were analyzed by in situ hybridization, MHC class II RNA transcripts were detected in cells near the lesion but not in cells that were infected with VZV. VZV infection inhibited transcription of interferon regulatory factor (IRF-1) in the IFN-γ signaling pathway and expression of Stat1a and Jak2 proteins. The inhibition of MHC class II expression on VZV-infected cells in vivo may transiently protect cells from CD4 T-cell immune surveillance, facilitating local virus replication during the first few days of cutaneous lesion formation during primary or recurrent VZV infection, and could allow a period of viral replication in skin cells even when the host has VZV-specific CD4 T cells. VZV also interferes with the cell signaling processes that signal the initial induction of the IFN-α/β response through a mechanism dependent upon the IE62 protein. Conversely, VZV induced upregulation of Stat3 and production of the anti-apoptotic protein survivin [67,68]. Stat3 induction was required for the pathogenesis of skin infection, indicating that VZV, a non-oncogenic herpesvirus, has the same effect known to occur in EBV- and KSHV-infected cells.

The host response

Primary VZV infection is associated with the development of virus-specific IgG and IgM antibodies and the acquisition of cellular immunity, which can be demonstrated by proliferation of T cells that are stimulated with VZV antigens in vitro. Although VZV IgG antibodies can neutralize virus infectivity and function in antibody-mediated cellular cytotoxicity, humoral immunity seems to be less important in the host response to VZV than cell-mediated immunity. Progressive varicella occurs in immunocompromised children despite the production of VZV IgG and IgM antibodies, whereas these children fail to develop VZV-specific T-lymphocyte proliferation [69]. Immunocompromised patients, including HCT recipients, develop VZV reactivation in spite of high concentrations of circulating antibodies to VZV. No quantitative relationship between VZV antibody titers in the donor or the recipient and the subsequent development of herpes zoster has been established in HCT patients [70]. A retrospective study examined anti-VZV IgG titers after HCT and also measured VZV DNA copy numbers by real-time PCR during clinical VZV reactivation using cryopreserved serum samples [71]. No significant difference was found between anti-VZV titers in patients with VZV infection and in those without VZV infection at each time point after HCT. However, patients with disseminated zoster tended to have lower pre-existing anti-VZV titers and higher serum VZV DNA copy numbers than those with localized zoster cases. A strong inverse correlation was found between pre-existing anti-VZV titer and serum VZV DNA at onset. Therefore, it was concluded that pre-existing antibody does not prevent the development of VZV reactivation in HCT recipients but may contribute to decreased viral load at onset. Periods of diminished VZV-specific T-lymphocyte proliferation have been correlated with an increase in susceptibility to herpes zoster among immunocompromised patient populations, including HCT recipients. In the individual patient, the loss of T-cell proliferation to VZV is a necessary, but not a sufficient, condition for symptomatic reactivation. Conversely, VZV-specific T-lymphocyte proliferation has been correlated with a decreased risk of herpes zoster.

Analyses of VZV-specific cell-mediated immunity have demonstrated a gradual recovery of T-cell proliferation to VZV antigens, with a larger percentage of HCT patients having detectable responses as the interval following transplant increases [4,17,61,72,73]. The interval to recovery may be shorter in autologous HCT recipients. This reconstitution of cell-mediated immunity to VZV antigens is generally observed by 9–12 months after HCT, which correlates with the time when VZV reactivation and susceptibility to severe VZV disease become less common. In HCT patients, IFN-γ production was associated with the recovery of T-cell proliferation to VZV antigen and increased with time following transplantation. Interleukin (IL)-10 production by PBMC stimulated with VZV antigen was also observed consistently after HCT and was highest in patients who recovered T-cell proliferation to VZV antigen [72].

When VZV T-cell proliferation responses were followed prospectively in unvaccinated patients in a study of inactivated varicella vaccine, autologous transplant patients had a mean VZV stimulation index of 9.9 ± 2.32 within 30 days before transplantation, responses were undetectable at 30 days, and then increased to 8.0 ± 1.63 by 90 days; mean responses continued to increase over the first year (Figure 89.5) [32]. Evaluation of VZV immunity at 6 months after transplantation using a quantitative flow cytometry method showed that the frequencies of CD4 T cells that made tumor necrosis factor-alpha (TNF-α) in response to VZV stimulation was 0.19%, compared with 0.30% in VZV immune adults without underlying disease; the mean percentage of CD4 T cells that made IFN-γ was 0.11%, which was equivalent to frequencies in healthy adults [32] (Figure 89.6). These analyses

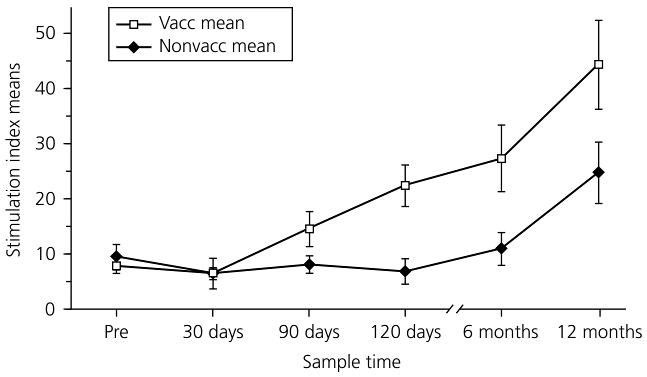

Figure 89.5 CD4 T-cell proliferation in response to VZV antigen. T-cell proliferation in response to VZV antigen, measured as the stimulation index, is shown as the mean stimulation index (*y*-axis) for vaccinated (□) and unvaccinated (◆) participants; the time of immunologic evaluation is shown on the x-axis in relation to time of HCT. Inactivated varicella vaccine was given pre-transplant and at 30, 60, and 90 days; the stimulation index for vaccinees at 30 days represents responses after the pre-transplant dose; at 90 days, three doses had been given, and at 120 days, 6 months, and 12 months, vaccinees had received four doses. The error bars represent standard errors. The numbers of patients tested at each time point were as follows: pre-transplantation, 58 unvaccinated/53 vaccinated; 30 days, 50 unvaccinated/49 vaccinated; 90 days, 43 unvaccinated/42 vaccinated; 120 days, 34 unvaccinated/39 vaccinated; 6 months, 30 unvaccinated/34 vaccinated; 12 months, 27 unvaccinated/33 vaccinated. Figure 89.6 Intracellular production of interferon-gamma (IFN-γ) or tumor necrosis factor-alpha (TNF-α) in T cells incubated with VZV. The percentage of CD4$^+$ T cells that expressed CD69 and intracellular cytokine, IFN-γ (black bars) or TNF-α (gray bars), was determined at 6 months after HCT in 19 vaccinated and 19 unvaccinated patients. Results are shown as mean percent responder cells ± standard error. Differences in VZV-specific responder cell frequencies in vaccinated and unvaccinated subjects were analyzed by unpaired *t*-test: for IFN-γ, $p = 0.07$; for TNF-α, $p = 0.03$. excluded patients who developed herpes zoster, indicating that VZV-specific T-cell responses can recover either as a result of subclinical VZV reactivation, as documented by VZV PCR testing of HCT recipients who had no signs of infection, or through re-expansion of memory T-cell populations that persisted through the preparative regimen for transplantation [61]. In this prospective study, the risk of zoster was reduced by 19% per unit increase in stimulation index (SI) >1.6; an SI >5.0 correlated with >93% protection [32]. Pre-transplant immunity in both the donor and the recipient may facilitate the reconstitution of VZV-specific cell-mediated immunity [74].

Nevertheless, it is apparent that the recovery of virus-specific cellular immunity is delayed for months and recovery of VZV-specific T-cell immunity often does not occur until after the patient has had an episode of herpes zoster, which provides in vivo re-exposure to VZV antigens. Meyers et al. detected T-lymphocyte proliferation to VZV in 16 of 18 patients (89%) following symptomatic recurrences of VZV compared with 15 of 29 patients (51%) who did not develop herpes zoster [4]. When herpes zoster occurs, HCT recipients show an increase in VZV-specific CD4 T-cell proliferation. We found that the mean SI response before onset of herpes zoster was 2.2 ± 0.4 compared with 28.1 ± 6.68 when the episode of VZV reactivation had resolved [32], which likely explains why HCT recipients are usually not susceptible to repeated episodes of herpes zoster.

During the first year, HCT patients recover cytotoxic T cells that recognize and lyse autologous target cells expressing VZV proteins [61]. About 50% of HCT patients showed recovery of VZV-specific cytotoxic T-lymphocyte (CTL) function when tested at a mean of 155 days after transplant (Figure 89.7). However, the mean precursor frequency of T-lymphocytes that recognized the VZV IE62 protein or glycoprotein E (formerly designated gp I) was more than twofold lower among HCT recipients than the frequency of CTLs that recognized these viral proteins in PBMCs from healthy immune subjects. In these experiments, cultures from HCT recipients showed a significant reduction in the proliferation of CD4$^+$ T cells compared with the pattern of cell phenotypes in cultures from healthy subjects. CD8$^+$ T cells predominated in VZV-stimulated cultures, reflecting the relative increase in circulating CD8$^+$ T cells that is common after HCT. Although CD8$^+$ T-lymphocytes have been defined as the "classic" cytotoxic effecter cell, human CD4$^+$ cells also function effectively as antiviral CTLs against many viruses, including VZV [75]. The diminished CD4$^+$ T-cell response to VZV antigen may explain why the overall frequencies of CTL precursors specific for the IE62 or gE (gp I) proteins remained significantly lower after HCT than in healthy, VZV immune individuals. Helper and cytotoxic T-cell responses specific for the IE63 protein and also proteins encoded by open reading frames 4 and 10 are maintained for decades after primary VZV infection in the intact host [76,77], and their absence could be related to the high risk of VZV reactivation causing herpes zoster.

In contrast to virus-specific T-cell immunity, natural killer (NK) cell activity comparable to that of healthy subjects is recovered during the first few months after HCT [78]. Some HCT recipients had a predominance of NK cells, expressing CD16 surface antigen, in assays for cytotoxicity against VZV-infected targets [61]. The importance of NK cells in the host defense against VZV has been exemplified by cases of severe or fatal disseminated VZV infection in patients with an absence of circulating NK cells during the VZV infection or with innate NK cell deficiencies [79–82]. The capacity of lymphocytes from some HCT patients to lyse targets expressing VZV proteins by a mechanism that is not antigen specific may help to limit VZV replication prior to the recovery of virus-specific T cells.

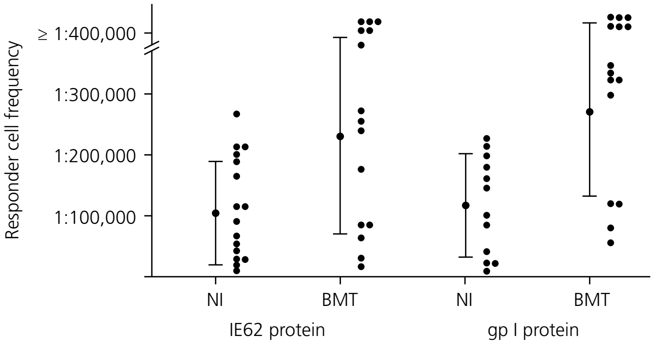

Figure 89.7 Precursor frequencies of cytotoxic T-lymphocytes (CTLs) specific for the immediate early protein (IE62) and glycoprotein I (gp I) of VZV in bone marrow transplant (BMT) recipients and healthy subjects (NI). The mean ± standard deviation for precursor frequency estimates are indicated next to the individual data points (dark circles) generated by testing individual BMT recipients and healthy immune subjects. Clinical manifestations

Primary VZV infection

The diagnosis of varicella is usually suspected clinically in both high-risk and healthy children when the characteristic vesicular exanthem appears [3,24,83,84]. The interval from exposure of the non-immune child to the appearance of the rash is about 14 days, with a range of 10–21 days; the incubation period may be shorter in immunocompromised children.

Because of its low incidence, specific descriptions of the clinical course of varicella after HCT are limited, but it is reasonable to generalize from the literature about varicella in other high-risk populations [83,84]. The initial manifestations of varicella in immunocompromised children are similar to those observed in healthy children. Prodromal symptoms may precede the rash by 24–48 hours, usually consisting of headache, irritability, malaise, and fever. Cutaneous lesions most often appear first on the scalp, face, or trunk, and are usually pruritic. Each lesion begins as a small erythematous macule that evolves into a vesicle of 1–4 mm diameter, on an irregular erythematous base, the classic "dewdrop on a rose petal." In high-risk children, including HCT recipients, the vesicles may be unusually large and can involve deeper skin layers. Vesicles on mucous membranes, including the conjunctiva, the oropharynx, the rectum, or the vagina are common even among otherwise healthy children. Varicella is typically accompanied by low-grade fever but temperature elevations may be as high as 40.5 ° C in high-risk patients, and fever often persists beyond the usual 3–4 days.

New vesicle formation typically continues for about 3 days, with a range of 1–7 days, among healthy children. This phase is often prolonged in immunocompromised children, with more than half of patients developing new lesions for more than 7 days [84]. Although the majority of immunocompetent children with varicella have fewer than 500 lesions, it is not unusual for patients on immunosuppressive therapy to develop more than 1500 lesions. Successive crops of varicella vesicles develop in a centrifugal pattern, appearing last on the extremities. These later crops of lesions tend to be more extensive in immunocompromised patients, and may involve the palms and soles in addition to arms and legs. In lesions that are resolving normally, the vesicle fluid rapidly becomes cloudy and the lesion may develop an umbilicated appearance as it becomes crusted. Among healthy children, the lesions that erupt later in the disease sometimes resolve after a maculopapular phase, but many of the late lesions also progress through the vesicular stage in immunocompromised patients. In general, the time to complete crusting of lesions is prolonged. Extensive hypo-pigmentation and scarring may be seen as the crusts resolve, presumably because of the involvement of deeper layers of the dermis in immunocompromised patients.

Patients who acquire the infection during the first 9–12 months after transplantation appear to be at highest risk of developing severe varicella [1]. The potential complications of varicella after HCT can be anticipated from the clinical experience with primary VZV infection in other immunocompromised patient populations. HCT recipients can be compared with patients whose immunosuppression is due to treatment of lymphoproliferative malignancies or solid tumors. In one large series of pediatric cancer patients, 32% developed visceral dissemination in the course of varicella, with VZV infection of the lungs, liver, and central nervous system (CNS) [83]. The mortality rate was 7% overall, with an increase to 25% in patients who developed varicella pneumonia. The risk for visceral involvement was significantly higher among patients whose absolute lymphocyte counts were less than 500/μL, and the rate of visceral dissemination increased to 71% when the lymphocyte count declined to less than 100 cells/μL. Visceral dissemination was associated with new lesion formation for a median of 10 days in more than half of patients who were evaluated before effective antiviral therapy for VZV was available. Based on the analysis of placebo recipients in the original studies of antiviral treatment of varicella in high-risk children, the mortality rate was 17%; 27% of the patients developed varicella pneumonia, 19% had hepatitis, and 6% had CNS disease [84].

Among the complications of primary VZV infection, varicella pneumonia is the most common cause of life-threatening illness. Respiratory symptoms, except for mild rhinitis and cough, are unusual in uncomplicated varicella and require urgent evaluation in the immunocompromised patient. Pneumonia most often develops within 3–7 days after the appearance of the rash and progresses rapidly to respiratory failure. Clinical signs of pneumonia may be limited to tachypnea, cough, and dyspnea with no accompanying abnormal findings by auscultation. The degree of hypoxemia may be marked even when abnormalities on the chest X-ray are minimal.

Varicella can be associated with abnormal liver function tests in the immunocompetent host but hepatic involvement is usually subclinical. In contrast, immunocompromised children are at risk of fulminant varicella hepatitis, with progression to hepatic failure.

Severe varicella is usually accompanied by signs of disseminated intravascular coagulopathy, including epistaxis, hematuria, and gastrointestinal bleeding. Hemorrhage into the cutaneous lesions is recognized as a poor prognostic sign in high-risk patients. Bleeding is most often due to disseminated intravascular coagulopathy and hepatic failure, but isolated thrombocytopenia can occur. Vomiting and abdominal pain are uncommon in children with uncomplicated varicella. Severe abdominal or back pain should be considered a sign of life-threatening infection, and may be associated with syndrome of inappropriate antidiuretic hormone (SIADH) secretion in the absence of any obvious CNS disease. This atypical presentation of VZV infection has been reported after HCT [85,86]. Although the pathogenic mechanism is not understood, disseminated VZV infection can cause pancreatitis and disease of the gastrointestinal tract, such as esophagitis, which may account for these symptoms, or pre-eruptive infection of sensory ganglia may occur. Varicella meningoencephalitis is unusual in immunocompromised children but when it occurs, it is usually associated with other signs of visceral involvement. Some patients develop a rapidly deteriorating course progressing to death. Symptoms of CNS disease most often occur between 2 and 6 days after the eruption of the rash and can progress rapidly to coma. Encephalitis may precede the appearance of the rash [87]. The clinical signs include vomiting, headache, altered sensorium, and seizures. The cerebrospinal fluid (CSF) usually shows a mild to moderate pleocytosis and elevated protein. SIADH may occur in patients who have meningoencephalitis [88].

Severe hypertension is a poor prognostic sign in immunocompromised patients with varicella. The mechanism is uncertain except in cases that are associated with nephritis. Adrenal cortical necrosis is noted at autopsy in patients with disseminated VZV infection.

In addition to complications directly related to viral replication, secondary bacterial infections are a risk in immunocompromised patients with primary VZV infection, as they are in otherwise healthy children. *Staphylococcus aureus* and *Streptococcus pyogenes* (group A streptococcus) are the most common pathogens, causing cellulitis, subcutaneous abscesses, and lymphadenitis. Varicella gangrenosa, a very rare syndrome of necrotizing fasciitis caused by *S. pyogenes*, is life threatening even in the intact host. Secondary bacterial infection of sites other than skin, including bacterial pneumonia, septic arthritis, and osteomyelitis, may follow varicella. Staphylococcal sepsis can occur, and children with indwelling catheters can develop line-related infections.

Although information is limited, varicella occurring late after HCT is usually not associated with complications. Four children who had varicella 2 years after transplantation had clinical disease that resembled primary VZV infection in children with no immunodeficiency, and four children who developed varicella 105–350 days after HCT had no complications [1,74]. However, progressive varicella with severe pneumonia was reported in one child who acquired varicella 6 years after successful HCT [89].

Recurrent VZV infection

Localized herpes zoster

Localized herpes zoster is the most common clinical presentation of VZV infection in HCT recipients who are seropositive at the time of transplantation, accounting for 85% of cases in 231 HCT recipients in the study by Locksley et al. [1]. The rash of localized herpes zoster is usually preceded by pain and paresthesias in the involved dermatome [5,84,90]. These symptoms may begin as long as 5 days before the eruption and vary from mild discomfort to very severe debilitating pain. The etiology of the initial pain is sometimes misdiagnosed as pleurisy, myocardial infarct, acute abdomen, or renal colic. In some instances the prodrome is not followed by any skin eruption [62], but a typical antibody response or viremia as detected by PCR is observed; this syndrome is referred to as "*zoster sine herpete*" [91,92]. In healthy subjects, herpes zoster involves the thoracic dermatomes in about half of the cases, and cranial nerve disease occurs in 13–20% of cases [84]. Recurrent VZV affects similar dermatomes in HCT patients, with thoracic dermatomal disease in 41–47% of cases and cranial nerve involvement in 16% (Table 89.3) [1,22,93].

Table 89.3 Distribution of dermatomal involvement with herpes zoster in HCT recipients and healthy individuals with recurrent VZV infections

	HCT recipients[a]	Healthy individuals[b]
No. of patients	195	116
Dermatomes involved (%):		
Cranial	16	15
Cervical	17	22
Thoracic	47	53
Lumbar	20	18
Sacral	12	8
Dissemination (%):		
Cutaneous	23	0
Visceral	13	0
Mortality (%)	7	0

The cutaneous lesions of localized herpes zoster appear as clusters of varicella-like vesicles in one or several sites anteriorly and posteriorly along the dermatome; typically, the lesions do not cross the midline, but some cases of bilateral dermatomal involvement have been described. Discrete vesicles often enlarge to form confluent lesions. In immunocompromised patients, including HCT recipients, the local vesicular eruption may be very extensive, evolving to occupy the whole dermatome;, the lesions may become hemorrhagic, and the duration of cutaneous disease is prolonged [84]. In the normal host, new lesion formation usually continues for 3–7 days followed by a phase of pustulation and crust formation; complete healing is expected by 2–3 weeks. In high-risk patients, the average time for cessation of new lesion formation was 8 days, and crusting was not complete until an average of 18 days. Immunosuppressed patients may occasionally develop a chronic cutaneous reactivation of VZV that persists for months [90,94]. As clinical experience with severely immunocompromised patients due to human immunodeficiency virus infection increases, knowledge about the spectrum of disease caused by VZV continues to expand [95]. Many of these complications are now recognized in HCT recipients with VZV reactivation.

When VZV reactivation involves cranial nerves, complications are more likely in both immunocompromised and immunocompetent patients [3]. In one series, corneal damage, facial scarring, cranial nerve VII palsy, or hearing loss occurred in 35% of patients [1]. The distribution of the ophthalmic branch of the trigeminal nerve is a common site of herpes zoster. The development of vesicular lesions on the nose is a sign of involvement of the ophthalmic branch and indicates a risk for ocular complications. The clinical findings of ocular herpes zoster include conjunctivitis, keratitis, anterior uveitis, or, rarely, pan-ophthalmitis (reviewed in [96,97]). Although corneal lesions are common, blindness is an unusual complication of herpes zoster ophthalmicus. Loss of vision associated with herpes zoster is usually secondary to retrobulbar neuritis. Although it is less common than CMV retinitis, chorioretinopathy caused by VZV is observed after HCT. Progressive outer retinal necrosis (PORN), a distinct form of VZV necrotizing chorioretinitis, is found almost exclusively in patients with acquired immunodeficiency syndrome, but cases of VZV-related PORN after allogeneic HCT have also been reported [98,99]. VZV reactivation may produce facial palsy when it involves cranial nerve VII. Herpes zoster oticus is associated with VZV reactivation from the geniculate ganglion, producing the Ramsay Hunt syndrome with unilateral deafness and vestibular symptoms. Oral lesions of the palate may develop without any cutaneous lesions when the second branch of cranial nerve V is affected.

Cerebral angiitis is a syndrome of cerebral vascular inflammation with thrombosis and microinfarcts associated with VZV reactivation in cranial nerve ganglia (reviewed in [100]). In severe cases, massive thrombosis with contralateral hemiparesis may result [101]. Infarct in the distribution of the middle cerebral artery can be demonstrated by computed tomographic scan. Pathologic findings include a granulomatous inflammatory process in the arterial wall, mononuclear cell infiltrates, vascular necrosis, and viral particles within the smooth muscle cells of the affected arteries. The syndrome is rare and there is no evidence that HCT or other immunocompromised patients are at increased risk for cerebral angiitis. However, it is important to recognize this complication in patients who develop hemiparesis about 6–8 weeks after the symptoms of herpes zoster.

When the anterior horn cells are involved in VZV reactivation, inflammation and necrosis may follow with resulting motor deficits in about 10% of otherwise healthy individuals with cervical, thoracic, or lumbosacral zoster [92]. Transverse myelitis and ascending paralysis are rare neurologic syndromes caused by recurrent VZV infection with or without immunosuppression, but the immunocompromised patients tend to have poorer outcomes. In a review of 31 patients, all 14 immunocompetent patients had good outcomes, whereas only eight out of 17 immunocomopromised patients had good outcomes [102].

Post-herpetic neuralgia (PHN)

Immunocompromised patients are at increased risk of PHN, which is the most common complication of herpes zoster in all patient populations. The definition of post-herpetic pain varies from any pain lasting after the crusts of the cutaneous lesions have disappeared to pain that persists more than 2 months. Estimates of the incidence of PHN vary depending upon the definition used. In one study of healthy individuals, 9% of patients with herpes zoster developed PHN, whereas Locksley et al. observed PHN in 25% of patients with herpes zoster after HCT [1] and Offidani et al. reported an incidence of 32% [25]. Koc et al. found that PHN and peripheral neuropathy were the most common complications of VZV reactivation after HCT, occurring in 68% of 100 consecutively identified cases [22]. The risk factors associated with PHN after VZV infection among HCT recipients were evaluated by Onozawa et al. [103]. Advanced age was the only risk factor noted in autologous HCT, but advanced age, male gender, and GVHD prophylaxis with a tacrolimus-based regimen were associated with increased risks for PHN in allogeneic HCT [103]. PHN is uncommon in children, even in those who are immunocompromised [90,104,105]; only 2–3% of pediatric HCT recipients who developed herpes zoster have persistent pain [24].

Secondary bacterial infection of skin lesions and local scarring are common in HCT recipients with herpes zoster, occurring with an incidence of 17 and 19%, respectively.

Cutaneous and visceral dissemination

In contrast to otherwise healthy subjects, HCT patients often develop cutaneous dissemination, defined as more than five vesicular lesions beyond the primary dermatome. Cutaneous dissemination has been reported in 17–24% of HCT recipients and was equally common among those who had recurrent VZV during the early or late period after transplant [1,22]. HCT recipients are also at risk of visceral dissemination during episodes of VZV reactivation (Figure 89.1). Since it is a sign of VZV infection of circulating lymphocytes, cutaneous dissemination provides a marker for the risk for visceral dissemination. However, visceral dissemination also occurs in patients whose cutaneous lesions are localized to the primary dermatome. Without antiviral therapy, visceral dissemination was observed in 13% of HCT patients with herpes zoster [22]. The potential sites of visceral dissemination with recurrent VZV are the same as those with disseminated primary VZV infection. The clinical complications that result include pneumonia, hepatitis, disseminated intravascular coagulopathy, and encephalitis. The mortality that accompanies VZV reactivation is almost always due to viral pneumonia, but fatal fulminant hepatitis and disseminated intravascular coagulopathy without VZV pneumonia have been reported [106]. An early study showed that acute GVHD is the only risk factor associated significantly with VZV dissemination [1]. An episode of zoster might trigger dermatomal GVHD as an isotopic response [107]. VZV has also been identified as the causative agent of late interstitial pneumonia in HCT patients with chronic GVHD [108].

Occasionally HCT recipients present with signs of visceral dissemination 24–96 hours before the localized cutaneous eruption of recurrent VZV becomes evident, resulting in delayed diagnosis, or misdiagnosis as GVHD or other complications [109–111]. Among these patients, the clinical presentation is characterized by abdominal pain, often mid-epigastric or periumbilical, with or without associated nausea, vomiting, or fever. Pancreatitis, hepatitis, gastrointestinal hemorrhage, intestinal necrosis, disseminated intravascular coagulopathy, and SIADH have been reported in patients with abdominal symptoms preceding the rash [63,85,109–112]. In particular, a "triad" of severe abdominal pain, SIADH, and disseminated zoster has been described in HCT or other immunocompromised patients [111,113,114]. In a series of 10 cases, patients had abdominal pain and elevated aminotransferases and pancreatic enzymes, associated with nausea (60%), fever >38 °C (60%), and vomiting (50%) [115]. Four patients had skin rash, which appeared at an interval of 4–14 days after the onset of abdominal pain. Five patients had pneumonitis and VZV infection was fatal in five cases. Visceral dissemination can also occur without any signs of cutaneous disease [116]; in those cases, VZV PCR might aid in the diagnosis [62,113]. In the study of Locksley et al. [1], three HCT patients had fatal VZV infection and no skin lesions during the course of their illness despite evidence of widespread organ infection at autopsy. In a retrospective review [33] of 310 children undergoing HCT in a single institution over a 7-year period, 61 of 201 (32%) allogeneic and 10 of 109 (9%) autologous HCT recipients developed zoster. Of 37 with available data on alanine aminotransferase (ALT) values 4 weeks preceding the clinical diagnosis of zoster, 22 (59%) patients experienced a rising ALT level, unassociated with GVHD. Hence, although there are many causes of elevation of transaminases and abdominal pain post-HCT, the possibility of VZV reaction should be considered, especially among those with increased risk factors for zoster, to allow for earlier diagnosis and therapeutic intervention [33].

Immunosuppression also predisposes to CNS infection with recurrent VZV, although symptomatic neurologic complications of herpes zoster are rare [117,118]. Two of 100 consecutively identified patients with recurrent VZV after HCT developed VZV encephalitis [22]. From the series of 310 children with HCT [33], three of 73 patients for whom sufficient information was available had CNS involvement. Despite its rare occurrence, cases of fatal VZV encephalitis have been reported [119]. In some cases, neurologic symptoms preceded eruption of skin lesions [87]. In evaluating these patients, it is important to note that abnormal CSF findings are common even in immunocompetent patients with herpes zoster. Lymphocytic pleocytosis and elevated protein were observed in about 40% of healthy individuals who had no abnormalities by neurologic examination, whereas the incidence of herpes zoster-associated encephalitis is estimated to be only 0.2–0.5% in this population [20,120,121]. The clinical symptoms and signs of CNS disease are headache, photophobia, meningismus, and altered state of consciousness [120,121]. The neurologic symptoms usually appear within a few days after the exanthem. The temperature is usually normal or mildly elevated. Seizures are rare but the electroencephalogram may show diffuse slowing or epileptiform activity.

As would be expected, the occurrence of visceral dissemination increases the mortality of recurrent VZV infection substantially, from an overall death rate of 7% to 55%. The mortality rate is higher in patients who develop both pneumonia and encephalitis than in those patients who have encephalitis only.

Atypical non-localized herpes zoster

Atypical non-localized herpes zoster after HCT is sometimes categorized as varicella because the HCT recipient is presumed to lack VZV immunity, regardless of prior immune status. However, identifying the syndrome as a distinct clinical presentation is useful because the pathogenesis of infection and the timing of the host response may be affected by differences between the endogenous and exogenous routes of infection and residual immunity may modify the clinical course. The incidence of atypical non-localized herpes zoster is variable, with reports of its occurrence ranging from none to as many as 25% of episodes of VZV reactivation after HCT. Clinically, patients with atypical non-localized herpes zoster have cutaneous vesicles that are identical with those of varicella. The number of lesions is variable but the eruption is often extensive, involving face, trunk, extremities, palms, and soles. This syndrome occurs in both autologous and allogeneic HCT recipients, accounting for 21% of episodes of recurrent VZV in one series [20]. The morbidity of untreated infection is high, with 45% of patients developing visceral dissemination, resulting in a mortality rate of 28% during the period before antiviral therapy was available [1].

Second episodes of recurrent VZV

Second episodes of VZV reactivation after HCT are uncommon. About 2% of patients had two episodes of herpes zoster, occurring at an average of 25 months after transplantation, with a range of 4–41 months. Most of the reported second episodes after HCT have involved the same dermatome but reactivation from another ganglia may occur [1].

Subclinical reactivation of latent VZV

The occurrence of subclinical VZV reactivation in HCT recipients has been shown by using a PCR method to demonstrate cell-associated VZV viremia [61]. Subclinical VZV reactivation was detected in 19% of 37 HCT patients who were screened randomly and had no signs of infection. Two of the seven patients who had subclinical VZV viremia developed clinical signs of herpes zoster subsequently, at intervals of 60 and 130 days later. Three patients who had subclinical VZV viremia between 17 and 85 days after HCT had cleared the cell-associated viremia when they were retested by VZV PCR; two patients were not re-evaluated by VZV PCR but did not develop herpes zoster. Thus, five of seven patients (71%) who had subclinical viremia did not progress to clinical infection.

Laboratory diagnosis

The diagnosis of VZV infection can be made by a variety of techniques, including viral culture, viral antigen detection, and viral DNA detection. Serologic testing is useful to demonstrate that the patient has had prior primary VZV infection and is therefore harboring the virus in sensory ganglia, but serologic tests are not useful for the diagnosis of active VZV infection. PCR technology has revolutionized the diagnosis of many infectious diseases, including that of VZV, because it is sensitive and rapid. The caveat is that clinical specimens contain inhibitors that may cause false-negative results in PCR assays.

Viral isolation in tissue culture cells

VZV can be detected in clinical samples using standard tissue culture methods for viral isolation [122]. The highest yield for viral culture depends upon obtaining vesicular fluid along with infected cells from the base of the cutaneous lesion. Vesicular fluid can be collected in a tuberculin syringe or by using a cotton or a Dacron [poly(ethylene terephthalate)] swab. Swabs should be put in viral transport medium immediately, agitated, and pressed against the side of the vial to remove absorbed fluid; the swab should be taken out of the vial before it is sent to the laboratory. If storage for more than a few hours is required, the specimen should be kept on dry-ice or frozen at −70 °C; storing the specimen at −20 °C in a standard refrigerator freezer for 24 hours usually inactivates the virus.

The optimal recovery of infectious virus in tissue culture requires the use of diploid cell lines or human embryonic lung fibroblasts. The cytopathic effect appears within 2–4 days after inoculation. Since the average time to detection of the virus in tissue culture is 7 days, diagnosis by viral culture is not rapid enough to influence clinical decisions in most circumstances. The sensitivity of tissue culture for detection of VZV is also substantially less than for identification of HSV and CMV. Procedures such as centrifugation enhancement may shorten the time required to detect cytopathic effects. There are some differences in the morphology of plaques produced by VZV compared with these other herpesviruses but the identity of the virus isolate must be proved by immunofluorescence staining with virus-specific antisera. As in the case of CMV, the shell vial culture method improves the sensitivity of VZV isolation and permits earlier identification of positive specimens. This method combines centrifugation and staining with fluorescein-conjugated monoclonal antibodies to VZV; positive results may be available within 1–3 days after inoculation. VZV detection by tissue culture methods is less sensitive than the direct fluorescence antigen (DFA) test.

The likelihood of recovery of VZV from cutaneous lesions is directly related to the stage of the lesion, with clear vesicles being much more likely to be positive than specimens from lesions that have become pustular or crusted. Varicella lesions are usually positive for 3 days, whereas virus can be recovered for 1 week or longer in herpes zoster. VZV can be isolated from PBMCs by tissue culture inoculation of specimens from immunocompromised patients with recurrent and also primary VZV infections. In contrast to meningoencephalitis associated with primary VZV infection, the virus has been isolated from the CSF of patients with herpes zoster. Bronchial washings may yield VZV in patients with pneumonia. The lungs are the most common autopsy organ from which VZV has been isolated, but the virus has been recovered from many sites, including heart, liver, pancreas, gastrointestinal tract, brain, and eyes.

Direct detection of VZV antigens in infected cells by immunofluorescence

The optimal method for the rapid diagnosis of cutaneous VZV infection is to obtain epithelial cells from a fresh lesion and to stain the specimen using fluorescein-conjugated monoclonal antibodies to VZV antigens [122,123]. The VZV-specific monoclonal antibodies bind to viral proteins that are synthesized within infected cells; fixing the cells prior to staining makes the cell membrane permeable, allowing the detection of VZV proteins in the cytoplasm and the nucleus and also on the cell surface. This method is referred to as the DFA test. The most important step in obtaining the specimen is to disrupt the roof of the vesicle in order to collect intact cells from the base of the lesion. Cells can be recovered efficiently by rotating the blunt end of a wooden applicator stick in the unroofed lesion or by scraping with a scalpel and transferring the material to a glass slide. Unless at least five intact cells are visible on the slide, the specimen should not be considered adequate for processing by the DFA method. It is important to include parallel staining of a portion of the specimen with reagents to detect HSV as VZV and HSV lesions are often indistinguishable clinically, and to provide a control for the specificity of the assay. The proper interpretation of DFA slides requires experience; the most common error is to identify false-positive results because of lack of expertise at distinguishing background non-specific fluorescence. If the clinical course of the patient is not consistent with a diagnosis of VZV infection that was based on the DFA method, the laboratory result should be questioned. DFA and indirect immunofluorescence or immunoperoxidase methods can also be used to demonstrate the presence of VZV in properly prepared tissue sections of lung, liver, and other organs from patients with disseminated VZV infections.

Enzyme immunoassay methods are also useful for detecting VZV antigens in specimens from skin lesions [122]. When laboratory facilities for DFA testing are not available, the Tzanck stain and other cytologic methods can be used to detect multinucleated giant cells in a lesion scraping; however, it is essential to realize that false negatives are common and that these methods do not differentiate VZV from HSV infection. Herpesvirus particles can be detected by electron microscopy but few diagnostic laboratories are equipped to perform this procedure. The method is not rapid and the morphology of herpesviruses is too similar to distinguish these viruses by electron microscopy.

Viral DNA detection

VZV DNA sequences can be detected using radiolabeled or biotinylated nucleic acid probes for in situ hybridization or Southern blot procedures [39,124,125]. However, in recent years, PCR has become the diagnostic test of choice for detecting VZV in clinical samples from patients with varicella or zoster. PCR assays for VZV are commercially available for routine diagnosis and can be applied to blood, CSF, skin biopsies, and various other kinds of tissues [126,127]. PCR-based techniques have been used for VZV genotyping and to differentiate wild-type VZV strains from Oka vaccine strains in investigations of varicella outbreaks following immunization [128–130]. Furthermore, this technology is particularly useful for the early diagnosis of VZV infection in the CNS. Since CNS infection by different herpesviruses may lead to indistinguishable clinical manifestations, PCR assays to enable parallel detection of more than one of these herpesviruses have also been developed [131–133]. Other molecular methods under development to detect VZV DNA include loop-mediated isothermal amplification (LAMP) [134,135] and microarrays [136–138].

Serologic diagnosis

Serologic screening of prospective HCT recipients for VZV antibodies is a valuable tool to establish immune status before transplantation. Many serologic methods are available for measuring IgG antibodies to VZV [3,122]. The most sensitive serologic assay for the detection of VZV antibodies is fluorescent-antibody staining of membrane antigen (FAMA), but this is a research method only. Other methods that are relatively reliable for establishing immune status include enzyme-linked immunosorbent assay (ELISA) and anticomplement immunofluorescence (ACIF). Although the commercially available ELISA kits for detecting VZV antibodies have a high degree of specificity, they are not as sensitive as FAMA. These methods do not usually yield false-positive results, but 10–15% of immune individuals may be wrongly identified as not having had previous VZV infection. Complement fixation methods are not satisfactory for determining immune status. Latex agglutination is a relatively sensitive and specific method for establishing VZV immune status [139,140].

Although seroconversion can be documented with primary VZV infection and boosts in antibody titers accompany recurrent VZV, the serologic diagnosis of acute infection requires paired sera and is rarely helpful for clinical purposes. VZV IgM can be detected in patients with varicella, but the majority of patients with recurrent infection also produce VZV IgM, which can be detected intermittently in healthy asymptomatic individuals [141]. Therefore, testing for VZV IgM antibodies is not useful in clinical practice, and should not be used. The test is commercially available through some reference laboratories, but testing is rarely performed with the proper control of a known VZV IgM-positive specimen.

Quantitative antibody detection has been used to measure the immune response to VZV after vaccination in clinical trials of varicella vaccines. The immune response following natural infection is usually more robust, with VZV antibody titers up to >10-fold higher than those following vaccination. Glycoprotein (gp) ELISA assays that allow quantitative VZV antibody measurement have been developed to evaluate VZV-specific immune status [142,143]. A titer of 5 gp ELISA units/mL of gp ELISA VZV antibodies at 6 weeks post-vaccination in initially seronegative children has been proposed as an approximate correlation of protection from infection [142,144]. However, this method is not commercially available and is subject to false-positive results [145]. At present, there is no reliable serologic method to assess VZV immunity after varicella vaccination. Furthermore, the detection of VZV IgG antibodies after vaccination using commercially available methods does not provide evidence of protection against breakthrough varicella, which can be expected to occur in some vaccinated individuals with close exposure.

Antiviral therapy for VZV infection

Acyclovir

Acyclovir {9-[(2-hydroxyethoxy)methyl]-9*H*-guanine} has been the drug of choice for the treatment of primary and recurrent VZV infections. The antiviral activity of acyclovir against VZV follows the same pathway that mediates its interference with the replication of HSV. The metabolism of the drug to the triphosphate form by the viral thymidine kinase produces a compound that functions as a competitive inhibitor and chain terminator of viral DNA polymerase. However, although HSV-1 and HSV-2 isolates are usually inhibited in vitro by 0.125 and 0.215 μg/mL of acyclovir, respectively, the mean concentrations required to inhibit VZV isolates are often 0.82–4.64 μg/mL, with ranges as low as 0.3 and as high as 10.8 μg/mL [146].

The plasma concentrations achieved by the intravenous administration of acyclovir at doses of 10 mg/kg or 250–500 mg/m^2 range from 15 to 25 μg/mL [84]. These concentrations are several-fold above the in vitro inhibitory concentrations for most VZV isolates. In contrast, only about 20% of the oral dose of acyclovir is absorbed. Oral administration to pediatric patients at doses of 600 mg/m^2 given four times per day produced peak plasma concentrations of approximately 1.0–1.5 μg/mL [147]. An oral dose of 200 mg of acyclovir given five times per day to adults (approximately 115 mg/m^2 for an adult male) produces plasma concentrations of approximately 0.5 μg/mL; increasing the unit dose to 600 mg resulted in plasma concentrations of 1.3 μg/mL [148]. Thus, acyclovir concentrations required to inhibit some VZV isolates can be expected to be significantly above the mean peak plasma concentration achieved by oral dosing.

Antiviral treatment of varicella

The administration of intravenous acyclovir to immunocompromised children with varicella has the potential to terminate the cell-associated viremia that produces malignant progressive varicella in these patients and to prevent the onset of varicella pneumonitis, each of which is correlated with a high risk of fatal infection [3,5,83,149]. The dosage of intravenous acyclovir for varicella in high-risk patients is 500 mg/m^2 or 10 mg/kg given every 8 hours, with administration continuing for 7–14 days. When this dosage was tested in placebo-controlled trials, the effect of the drug on the number of days to defervescence and resolution of cutaneous lesions was not significant, but varicella pneumonitis was prevented in the acyclovir recipients [150,151]. Primary VZV infection in HCT recipients occurring within the first year after transplant should be considered to require intravenous acyclovir therapy. The goal of antiviral therapy for varicella in high-risk patients is to initiate drug treatment within 72 hours after the appearance of the cutaneous rash. Parents and patients need to be educated about the typical appearance of varicella lesions because many cases occur without any known exposure, and prompt diagnosis during the early phase of infection is important to the success of antiviral therapy.

Immunocompromised children who have been vaccinated are at risk for breakthrough vesicles and parents should also be educated about the signs and symptoms, even though vaccination is expected to provide some protection from severe disease. Since there are other causes of vesicular rashes in childhood and in immunocompromised patients, the clinical diagnosis should be confirmed by the laboratory using the DFA or PCR technique. Although most children do not have clinical signs of dissemination immediately, the interval during which preventive therapy can be initiated is very short. The decision to initiate antiviral therapy must be made before progression of the rash becomes obvious, because visceral dissemination takes place at the same time. The average period to onset of varicella pneumonitis is 6 days, with most cases occurring within 4–8 days among untreated high-risk patients. In addition to preventing life-threatening dissemination, acyclovir therapy can also minimize the extent of the cutaneous disease and shorten the time to complete healing significantly [83]. More rapid resolution of the cutaneous lesions may also reduce the risk of secondary bacterial infections.

Immunocompromised children or adults who present with signs of disseminated VZV infection should receive immediate treatment with intravenous acyclovir. The efficacy of acyclovir for the treatment of established varicella pneumonia or other visceral sites of infection has not been determined in a controlled trial. Five recipients of placebo in the original acyclovir trial who developed pneumonitis were placed on the drug approximately 6–8 days after the appearance of the varicella rash, and all of these patients improved after initiation of the drug [151]. However, in another series, three of four high-risk patients who were not treated until at least 5 days after the onset of the cutaneous lesions had evidence of visceral dissemination at the initiation of treatment; all three patients had progressive varicella and two patients died [152].

Beyond 9–12 months after HCT, it may be acceptable to monitor the clinical course of varicella without giving acyclovir, assuming that the patient has no evidence of GVHD and is not receiving immunosuppressive therapy. However, given the predictable benefits of a short course of acyclovir for varicella, even in healthy children, its administration is justified.

Antiviral treatment of herpes zoster

Acyclovir has been shown to be effective for the treatment of recurrent VZV infection in immunocompromised patients in placebo-controlled trials and through extensive clinical experience with the drug. The dose of acyclovir is 500 mg/m^2 or 10 mg/kg given every 8 hours intravenously. Therapy should be continued for 7–14 days or for 2 days after cessation of new lesion formation, whichever provides the longer treatment course.

In a placebo-controlled trial, local progression and progression of cutaneous dissemination was terminated with acyclovir therapy [153]. One of 52 treated patients had progressive VZV disease compared with 11 of 42 placebo recipients. Treatment resulted in a shorter time to cessation of new lesion formation, more rapid crusting and healing, and prevention of cutaneous and visceral dissemination in patients who presented with localized herpes zoster (Figure 89.8). Acyclovir decreased the duration of local viral replication, with viral cultures remaining positive for VZV for only 4 days after the initiation of treatment. Based on this experience, acyclovir therapy initiated within 72 hours after the onset of VZV reactivation can be expected to reduce the duration of new lesion formation in HCT patients to approximately 3 days. On average, early antiviral treatment should cause the cessation of acute pain within 4 days, crusting of lesions by 7 days, and complete healing by 2–3 weeks (Figure 89.8). Although early acyclovir treatment is likely to produce the best results, clinical benefit can still occur when therapy is delayed for more than 3 days [153]. None of 29 immunocompromised patients whose therapy was initiated more than 3 days after the onset of the rash had progressive herpes zoster compared with three of 17 patients in the placebo group.

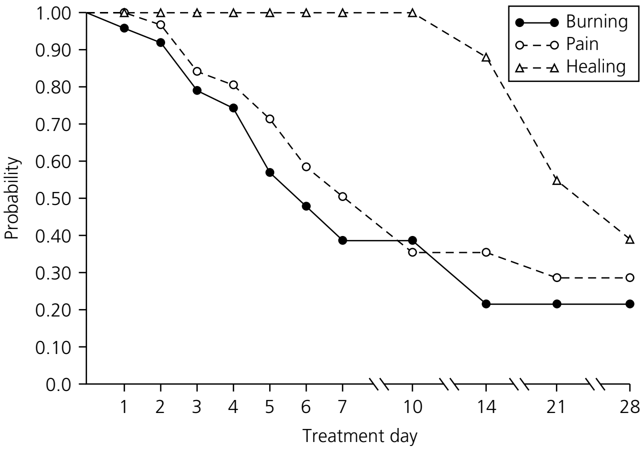

Figure 89.8 Probability of lesion burning (23 patients; •), of lesion pain (31 patients; ∘), and of not having total healing (31 patients; Δ) by treatment day. Source: Meyers et al. 1984 [277]. Reproduced with permission of Lippincott Williams & Wilkins.

Although the drug eliminates the life-threatening complications of VZV reactivation in most patients, relapse of herpes zoster is a clinical problem in some HCT patients who are treated with acyclovir. In one series, five of 40 patients (12%) developed new lesions with relapse occurring less than 4 days after treatment was stopped in three of the five patients [154]. Early acyclovir therapy may delay the recovery of VZV-specific immunity in some patients. Nevertheless, most patients respond to treatment with a second course of acyclovir.

The efficacy of oral acyclovir for herpes zoster in HCT patients has not been firmly established in prospective studies, but this route of administration is appropriate for selected patients who have localized herpes zoster occurring in the late period after HCT. The bioavailability of oral acyclovir is low, and this route of administration requires giving 800 mg per dose, five times per day. Most clinicians now prefer to use valaciclovir, the prodrug of acyclovir, or famciclovir, which have enhanced bioavailability (see below). Patients receiving oral acyclovir should be monitored for signs of progressive VZV infection and should be treated with the intravenous drug if complications arise. When patients are treated with the standard intravenous regimen, there is no need to provide further oral treatment after discharge. However, in some cases, the full course of therapy may be achieved by a combination of intravenous and oral agents. HCT recipients may have a higher rate of recurrence of pain after cessation of therapy.

Acyclovir toxicity

The safety of acyclovir has been established in numerous clinical trials. Although HCT patients also tolerate the drug well, the incidence of side effects is higher. In one series, gastrointestinal symptoms of nausea and vomiting occurred in 40% of treated patients [154]. Nephrotoxicity, defined as a 50% rise in serum creatinine, was also more common than in other patient populations treated with acyclovir; 10–25% of HCT patients receiving acyclovir are reported to have an abnormal serum creatinine, but these elevations may be caused by other medications given concurrently [154]. In any case, since acyclovir is excreted by glomerular filtration, other drugs that affect renal function, such as cyclosporine, can interact to cause elevated plasma concentrations of the drug.

The dosage and dose interval for acyclovir administration should be adjusted based on the relative impairment of creatinine clearance. The dosage interval should be lengthened to every 12 hours for clearances of 25–50 mL/min and to 24 hours for clearances of 10–25 mL/min; if the clearance is 0–10 mL/min, the dosage should be reduced to 250 mg/m^2, given every 24–48 hours. It is also important to maintain adequate hydration in patients receiving acyclovir to avoid precipitation of the drug in renal tubules. A few cases of acute neurotoxicity have been reported in patients with deficient renal clearance who were receiving acyclovir. Abnormal liver function tests should be considered possible evidence of VZV hepatitis rather than drug toxicity. Acyclovir does not have hematologic toxicity and does not interfere with engraftment in HCT recipients.

Resistance to acyclovir

Although VZV resistance to acyclovir is not common in HCT recipients, it has been reported in these patients and patients with the acquired immunodeficiency syndrome [155–157]. Among HCT recipients, the failure of VZV infections to resolve, or their recurrence shortly after antiviral therapy is discontinued, is usually a function of the limited host response and should not be attributed to acyclovir resistance in most cases. When it occurs, antiviral resistance is usually mediated by thymidine kinase mutations, but mutations of the viral DNA polymerase have also been reported [158,159]. Interestingly, thymidine kinase mutations can be both temporally and spatially compartmentalized. Brink et al. reported the finding of plasma samples with wild-type thymidine kinase sequences when CSF or skin vesicle fluid acquired on the same day contained mutant sequences [160]. Hence sampling for molecular diagnostics should be performed on plasma and also samples from other affected body sites whenever possible, if antiviral resistance is suspected.

Other antiviral compounds

Famciclovir and valaciclovir are nucleoside analogs and are prodrugs of penciclovir and acyclovir, respectively. Both have been licensed for the treatment of herpes zoster in the immunocompetent host [161–164]. Similarly to acyclovir, penciclovir [9-(4-hydroxy-3-hydroxymethylbut-1-yl)guanine] is phosphorylated by the viral thymidine kinase and acts as a competitive inhibitor of the viral DNA polymerase, but unlike acyclovir, it is not an obligate chain terminator. The advantage of these prodrugs is much better absorption after oral administration than acyclovir, coupled with a safety profile that resembles that of acyclovir; however, they are not useful for treating VZV infections caused by acyclovir-resistant strains [155–157]. Although controlled trials to establish the clinical efficacy of these antiviral agents in HCT patients have not been performed, valaciclovir or famciclovir may be useful in selected patients who are considered to be at low risk of visceral dissemination during recurrent VZV reactivation. Attention to the dosage of these very efficiently absorbed drugs is essential, since toxicity of valaciclovir, manifest as thrombocytopenic purpura and hemolytic uremic syndrome, has been reported in HCT recipients [165]. Plasma concentrations approach those achieved by intravenous administration of acyclovir unless the patient has altered gastrointestinal function, which may be an obstacle to their use in some HCT recipients. Famciclovir and valaciclovir require less frequent administration and are more convenient for patients, but these drugs are more expensive than oral acyclovir.

Foscarnet, a pyrophosphate analog, has antiviral activity against VZV through inhibition of the viral DNA polymerase and has activity against isolates that are not inhibited by acyclovir or famciclovir [95,155,166]. Its clinical use is complicated by potential nephrotoxicity and the emergence of resistance [167,168].

Cidofovir is a nucleotide agent that may be useful for resistant strains but clinical experience is limited. Serious side effects of this drug include severe nephrotoxicity, metabolic acidosis, neutropenia, and ophthalmic complications.

Ganciclovir [9-(1,3-dihydroxy-2-propoxymethyl)guanine (DHPG)] has in vitro activity against VZV that is equivalent to acyclovir, but clinical studies of its efficacy for the treatment of VZV infections have not been carried out because of its greater toxicity. However, it is possible that the administration of ganciclovir to HCT recipients who have CMV infection could alter the course of concurrent VZV infection.

Vidarabine, the first antiviral agent shown to have clinical benefit for the treatment of VZV infections in immunocompromised patients, inhibits VZV by a different pathway, but was less effective than acyclovir and is no longer available [154]. Brivudine, a nucleoside analog of thymidine and its arabinofuranosyl derivative sorivudine also have potent antiviral activities against VZV and HSV. A single daily dose of brivudine at 125 mg was found to be effective in the treatment of herpes zoster compared with acyclovir 800 mg five times per day or famciclovir 250 mg three times per day, all given orally [169,170]. However, the metabolite of brivudine and sorivudine blocks the degradation of the anticancer drug 5-fluorouracil (5-FU), resulting in the accumulation of 5-FU to toxic levels. The development of sorivudine was terminated in the United States because of such lethal interactions with 5-FU and the concern that it might be administered inadvertently to patients who were receiving this drug [171,172]. Brivudin is approved for sale in some European countries, including Germany and Italy, but its use is contraindicated in cancer patients taking 5-FU, its prodrugs (e.g. tegafur, capecitabine), or other antimetabolites. Brivudin is not licensed for use in the United States.

Human and recombinant leukocyte interferon were shown to have significant clinical efficacy in immunocompromised patients with herpes zoster in early studies and provide an alternative to the nucleoside analog drugs for the treatment of resistant VZV infection [173]. However, given the availability of other antivirals, this approach is now rarely employed, if at all.

It should be noted that despite the activities of these agents against VZV, there is no evidence that combinations of these antiviral drugs improve the treatment of VZV infection and adverse drug interactions may occur.

Anti-VZV drugs in development

A number of novel antivirals against VZV are currently under development, including the helicase–primase inhibitors (HPIs), bicyclic nucleoside analogs (BCNAs), an ester derivative of cidofovir, and a new nucleoside analog.

One of the novel HPIs, ASP2151 (also known as amenamevir), is a non-nucleoside oxadiazolylphenyl derivative with potent activities against VZV and also HSV-1 and -2. This drug is significantly more potent than acyclovir in vitro and in vivo (e.g. anti-VZV EC_{50} of ASP2151 at 0.038–0.10 μM compared with that of acyclovir at 1.3–2.7 μM) [174] and is active against acyclovir-resistant virus. It is orally available and has been evaluated in several clinical trials. A randomized, double-blind control trial showed that three-day or single-day courses of ASP2151 appear to be effective and safe options for the treatment of recurrent genital herpes compared with valaciclovir [175]. A dose-finding study that investigated the efficacy and safety of three different doses of ASP2151 in comparison with valaciclovir in subjects with herpes zoster was also completed, but no results have been reported (ClinicalTrials.gov Identifier: NCT00487682).

The BCNAs have emerged as the most potent anti-VZV agents reported, with in vitro anti-VZV activity at ≤1 nM concentration, at least 1000 times more active than acyclovir (reviewed in [176,177]). Whereas HPIs are equipotent against VZV and HSV, BCNAs are selective for VZV, as they require activation by VZV thymidine kinase-mediated phosphorylation, but are not recognized by HSV thymidine kinase. Furthermore, neither cellular cytosolic nor mitochondrial thymidine kinases can phosphorylate BCNAs, thus explaining their low toxicities [177,178]. FV100, the prodrug of a BCNA Cf1743, was well tolerated by healthy subjects in a randomized, double-blind, placebo-controlled trial that studied its pharmacokinetics and safety [179]. A phase II clinical trial to evaluate FV100 for the treatment of herpes zoster in comparison with valaciclovir was also completed in December 2010, but no results have been reported to date (ClinicalTrials.gov Identifier: NCT00900783). Despite the potency of BCNAs, thymidine kinase mutants of acyclovir or brivudine would likely confer cross-resistance to this class of antivirals [177].

CMX001 is a lipid ester of cidofovir with enhanced bioavailability and was also significantly more active against double-stranded DNA viruses (including herpesviruses) than cidofovir when tested in vitro [180]. The drug was found to be well tolerated by healthy volunteers [181]. When tested as salvage therapy in 13 immunocompromised patients with severe adenovirus infection, no serious side effects were attributable to CMX001 [182]. Early-phase clinical trials to evaluate its safety and tolerability in immunocompromised patients with CMV infection and with BK infection have been completed (ClinicalTrials.gov Identifiers: NCT00942305 and NCT00793598, respectively) and several other clinical trials to evaluate the safety and efficacy of this drug are ongoing. There are currently no clinical data that demonstrate the use of this drug for varicella or zoster treatment, but it might have a significant role in the treatment of acyclovir-resistant VZV, given its potency and safety profile.

Valomaciclovir is the diester prodrug of the acyclic guanosine derivative (*R*)-9-[4-hydroxy-2-(hydroxymethyl)butyl]guanine (H2G). It has been tested in a randomized, double-blind study for the treatment of herpes zoster in immunocompetent adults in comparison with valaciclovir [183]. Valomaciclovir was tested in three different doses (1000, 2000, and 3000 mg daily). The two higher doses were found to be non-inferior to valaciclovir 1000 mg three times daily for the primary efficacy measure of "time to complete crusting of the zoster rash by day 28." However, for some of the secondary endpoints (time to cessation of new lesion formation and time to cessation of pain by day 120), no valomaciclovir groups were non-inferior. Further studies to evaluate the potential of this drug for VZV treatment are needed.

Treatment of PHN

Although acyclovir is clearly beneficial for the treatment of acute herpes zoster, its effect on the incidence of PHN has been more difficult to establish. Varying definitions of PHN have complicated assessments of antiviral and adjunctive therapies. A meta-analysis of several placebo-controlled trials of oral acyclovir therapy for herpes zoster in otherwise healthy individuals indicated that long-term pain is diminished [184,185]; however, a more recent Cochrane review concluded that oral acyclovir treatment during the acute phase of zoster does not significantly reduce the incidence of PHN [186]. The fact that acyclovir ameliorates the acute pain associated with herpes zoster more effectively than long-term pain suggests that a different mechanism is responsible for PHN. Continued VZV replication is not likely to account for post-herpetic pain. Instead, it has been suggested that the initial neuronal infection and associated inflammation, which can persist for months, result in deafferentation, ectopic activity of damaged afferents nerves, and enhanced excitability of neurons relaying central pain signals (reviewed in [187]).

Current approaches to the management of PHN (reviewed in [187–189]) include opioid analgesics [190], tricyclic antidepressants [191–194], and antiepileptics such as gabapentin [195,196], pregabalin [197,198], and divalproex sodium [199]. Topical application of lidocaine or capsaicin in the form of patches or cream can also provide some relief.

Although the administration of corticosteroids orally or intrathecally as adjunctive therapy may have some benefits in relieving the zoster-associated pain during the acute phase of disease [200–202], steroid treatment is ineffective in preventing PHN [202,203]. However, intrathecal corticosteroids might provide relief to some patients with intractable pain from PHN [204]. Medical interventions to treat PHN are often used in combination, or sequentially, because no single approach is beneficial in most patients. The benefits of some other approaches, such as neuroaxial and sympathetic blockade [205], spinal cord stimulation [206], intravenous lidocaine [207], or cryotherapy [208], have not been convincingly demonstrated. A number of other agents (e.g. the selective serotonin reuptake inhibitors duloxetine and venlafaxine, tramadol, or tapentadol) have also been used in the treatment of neuropathic pain including PHN, but clinical data from randomized controlled trials are currently lacking [187].

Prophylaxis for VZV infection

Varicella zoster immune globulin

Varicella zoster immune globulin (VZIG) is a passive antibody preparation containing VZV IgG antibodies that is prepared from high-titer immune human serum. VariZIG (Cangene Corporation, Winnipeg, Canada) is currently the only VZIG preparation available in the United States and was approved by the US Food and Drug Administration (FDA) in December 2012 for postexposure prophylaxis of varicella in persons at high risk for severe disease. The product is lyophilized, and when reconstituted properly is an approximately 5% solution of IgG. The dosage is one vial (125 units) per 10 kg body weight given intramuscularly with the minimum dose of 62.5 units for pediatric patients who weigh ≤2 kg and the maximum dose of 625 units for patients who weigh >40 kg. If VariZIG is not available, an alternative would be intravenous immunoglobulin (IVIg), which can be administered at 400 mg/kg [209].

Passive antibody prophylaxis with VariZIG or IVIg is indicated following exposure of VZV seronegative, immunocompromised children or adults who have not had previous VZV infection, including HCT recipients [165,210]. HCT recipients are in general considered non-immune, regardless of previous history of varicella disease or varicella vaccination in themselves or in their donors. However, if varicella or zoster develops after transplantation, they should then be considered immune [210] and passive antibody prophylaxis would not be indicated after exposure. Passive antibody prophylaxis should be administration within 96 hours and preferably within 48 hours after exposure, although VariZIG can be administered up to 10 days after exposure [211]. Varicella exposure is defined as household contact, shared hospital room, or indoor play for at least 1 hour with a child who is in the contagious phase of varicella, which is the interval from 2 days before to 5 days after the onset of the rash. If a patient has received any of the commercial preparations of high-dose IVIg (≥400 mg/kg) for other indications within 3 weeks before the exposure, it is not necessary to administer VZIG [185,210]. The duration of protection after administration of passive antibody prophylaxis is unclear, but it is thought to last at least one half-life of the Ig, which is about 3 weeks. Therefore, a second dose of passive antibody prophylaxis should be given if a new exposure occurs more than 3 weeks after a dose of VZIG has been given [210]. Although the risk of VZV transmission from an individual with herpes zoster is low, close contact between an HCT patient who has never been infected with VZV and a patient with recurrent VZV lesions also justifies the administration of VZIG.

Clinicians must be aware that severe varicella develops in some immunocompromised patients despite the timely administration of VZIG. The incidence of varicella despite VZIG prophylaxis is significantly higher for children with household exposures than for those who have less prolonged contact with the index case, and the attack rate is affected by the VZV IgG titer of the preparation [212]. In a placebo-controlled trial of intravenous acyclovir, one of six (17%) placebo recipients who had received ZIG (zoster immune globulin) or ZIP (zoster immune plasma) before entry required reassignment to open drug because of progressive varicella [151]. In the St. Jude experience, the risk of varicella pneumonitis was reduced significantly by passive antibody prophylaxis but 11% of children developed pneumonia despite receiving ZIG, ZIP, or VZIG [83]. Because of these risks, HCT recipients who develop varicella should be treated with intravenous acyclovir even if passive antibody prophylaxis was given at the time of exposure.

Since the live attenuated varicella vaccine is recommended for universal administration to children in the United States at age 12–15 months, some children will have had vaccine-induced immunity before HCT [213]. These children should be given passive antibody prophylaxis for exposure to wild-type varicella because the protective efficacy of varicella vaccine is not defined in these circumstances. High-risk children may also have close exposure to an immunized child or adult who has breakthrough varicella caused by the wild-type virus or, rarely, to a healthy contact with a varicella vaccine-related rash. Immunocompromised children who have such an exposure should receive passive antibody prophylaxis. However, depending on the timing of administration after vaccination, contacts treated with passive antibody prophylaxis can still develop subclinical or clinical varicella. In an early study that evaluated the efficacy of VZIG in immunosuppressed children after household exposure to varicella, up to 60% developed clinical disease despite detectable VZV antibodies [212]. Based on reports of clinical experience but without controlled trials, some experts have recommended using acyclovir (or valaciclovir) in combination with passive antibody prophylaxis or alone as postexposure prophylaxis for VZV exposure in susceptible high-risk children [214–216]. There is no indication that passive antibody prophylaxis will reduce the risk of VZV reactivation after HCT in patients who have serologic evidence of prior VZV infection. Passive antibody administration is not effective for the treatment of herpes zoster.

Acyclovir prophylaxis

The efficacy of acyclovir prophylaxis for preventing recurrent VZV infection in HCT recipients has been evaluated in a number of studies [23,27,217–228], but only four of them were prospective

Table 89.4 Selected studies on antiviral prophylaxis for prevention of VZV infection after HCT

Study	Randomized, double-blind, placebo-controlled?	HCT type	Antiviral drug/dose[a]	Total duration of prophylaxis (months)	No. of patients on prophylaxis/ no prophylaxis	No. of patients with VZV reactivation during prophylaxis	Cumulative incidence of VZV reactivation from day 0 of HCT (treatment group/ control group)
Ljungman, 1986 [217]	Yes	Allogeneic	Acyclovir 1200 mg qd	6 months	20/22	0	20%/27% at 1 year

Klein, 2011 [228]	Yes	Allogeneic or autologous	Valaciclovir 1000 mg bid	4–24 months	22/26	0	NA

Abbreviations: bid, twice per day; qd, daily; q6h, every 6 hours; tid, three times per day; tiw, three times per week; NA, not available.

[a] Patients in these studies might receive a higher dose of oral acyclovir or intravenous acyclovir during the early phase of HCT (e.g. until engraftment) before being started on prophylaxis. Please refer to references for details.

[b] 28/143 patients received acyclovir only, and 115/143 patients received both ganciclovir and acyclovir. Ganciclovir was given to patients with CMV^+ donors from engraftment to at least day 84, or to those receiving ≥20 mg of prednisone for GVHD treatment. For those patients receiving ganciclovir, acyclovir prophylaxis recommenced at the completion of ganciclovir prophylaxis. (See [23] for details.)

[c] Cases occurred when patients were off acyclovir.

randomized, double-blind trials (summarized in Table 89.4). The dose of acyclovir employed ranged from 200 to 3200 mg per day, and valaciclovir was also used in some studies. Most of these studies gave prophylaxis for a duration of 6–12 months, or until the end of immunosuppressive therapy. Overall, the administration of acyclovir (or valaciclovir), even at low doses, can effectively prevent VZV reactivation during the prophylactic period. Among all these studies on >2000 patients combined, there were only a few cases of breakthrough zoster infection, compared with a 30–60% incidence of VZV reactivation without prophylaxis [1,22,24] (Table 89.4). However, whether acyclovir prophylaxis confers any long-term benefits is more controversial. Regardless of the acyclovir dose or duration employed, prophylaxis with acyclovir in general delays but does not completely prevent VZV reactivation. Several earlier studies using "higher" doses of acyclovir found that VZV readily reactivated after cessation of acyclovir prophylaxis, with accumulative incidence in subsequent years not significantly different from the placebo group [217–219,223]. For instance, patients who underwent allogeneic HCT were randomized to receive acyclovir 800 mg twice daily or placebo for 1 year after transplantation in a double-blind controlled trial of the efficacy of long-term acyclovir prophylaxis [223]. Acyclovir significantly reduced VZV infection at 1 year after transplantation, with a hazard ratio (HR) of 0.16, but the postintervention observation at 2, 3, and 5 years showed no statistical difference in VZV infection between the two groups. In contrast, several more recent studies [27,28,221,224,226] have found a reduced cumulative incidence of VZV reactivation among the prophylaxis groups after cessation of antiviral therapy. Furthermore, the severity of clinical symptoms associated with VZV reactivation was also reduced, with fewer patients developing disseminated disease or VZV-related complications and mortality [224,225]. Most of these studies used low doses of acyclovir [28,221,224,226], and it has been theorized that administration of very low-dose acyclovir might permit subclinical VZV reaction to allow the recovery of VZV-specific T-cell immunity [61]. However, the favorable outcomes of low-dose acyclovir prophylaxis are not universal [222] and have not been validated by randomized prospective studies.

The most recent guidelines [216], developed jointly by the Centers for Disease Control and Prevention (CDC), the Infectious Diseases Society of America (IDSA), the American Society for Blood and Marrow Transplantation (ASBMT), and other agencies for preventing infectious complications after HCT now recommend long-term acyclovir to prevent recurrent VZV infection for the first year after HCT among VZV-seropositive allogeneic and autologous HCT recipients. As VZV reactivation after cessation of acyclovir prophylaxis appears to occur predominantly in patients who are continued on or have resumed immunosuppressive therapy [221,224,226], acyclovir prophylaxis may be continued beyond 1 year in allogeneic HCT patients, until all systemic immunosuppressive drugs are discontinued and the CD4 count exceeds 200 cells/μL [216]. A prophylactic regimen of acyclovir 800 mg PO twice daily or valacyclovir 500 mg PO twice daily is recommended [216], although lower doses of acyclovir also appear to be effective, as summarized in Table 89.4. Although prolonged administration of low-dose antivirals for prophylaxis might enhance the emergence of VZV strains that are resistant to the drug, acyclovir-resistant VZV strains have been reported only rarely in HCT patients [158,160], and genotypic analyses failed to identify a cause of resistance in up to 50% of the isolates with clinical resistance to acyclovir [158,159]. Patients with breakthrough infection reportedly responded well to therapeutic doses of oral acyclovir, valacyclovir, or famiciclovir, or IV acyclovir, without any evidence of developing acyclovir-resistant mutants [224–226].

VZV vaccines

In 1995, a live attenuated varicella vaccine (Oka strain) was approved for administration to healthy children in the United States. Experience from the last 10–20 years, with tens of millions of doses administered over the pre- and postlicensure periods, has demonstrated the effectiveness and safety of this vaccine in the immunocompetent population. From various investigations, the overall vaccine effectiveness ranges from 71 to 100% against varicella and from 95 to 100% against moderately severe and severe disease [229–231]. After the implementation of universal childhood vaccination, the incidence of varicella declined by 90% and related mortality declined by 66% [232,233]. Two live, attenuated VZV-containing vaccines are available in the United States for prevention of varicella: a single-antigen varicella vaccine (Varivax; Merck) and a combination vaccine for measles, mumps, rubella, and varicella (ProQuad; Merck). In 1996, the Advisory Committee on Immunization Practices (ACIP) recommended one dose of varicella vaccine for children aged 12 months to 12 years, but two doses, 4–8 weeks apart, for those aged ≥13 years [234]. However, despite the success of the one-dose regimen with a vaccine effectiveness of 85%, varicella outbreaks continue to occur in highly vaccinated school populations [235]. Furthermore, a two-dose regimen was found to be significantly more effective than a single injection with a 10-year observation period [236]. In 2006, ACIP started to recommend two doses of varicella vaccine as opposed to one dose for children, and also all susceptible adolescents and adults [210]. A second dose is also recommended for all persons who received one dose previously. Following the implementation of two doses, the incidence of varicella further decreased from 48.7 cases/100,000 persons in 2005 to 24.5 in 2008 [237].

In May 2006, a live attenuated vaccine (Zostavax; Merck) was also approved in the United States for prevention of zoster and PHN in adults aged 60 years or older. This zoster vaccine is also based on the Oka-Merck strain, but each dose contains 19,400 PFU, compared with 1350 PFU in the varicella vaccine. In a large prelicensure study that enrolled 38,546 adults, the vaccine reduced the incidence of zoster by 51.3%. The burden of illness due to zoster and due to PHN was also reduced by 61.1% and 66.5%, respectively [238]. Based on a multicenter study conducted in approximately 22,000 people who were 50–59 years of age [239], the FDA further approved the use of Zostavax in adults of this age group in March 2011. However, ACIP has declined to recommend its use among adults aged 50–59 years and reaffirmed its existing recommendation that herpes zoster vaccine be routinely recommended for adults aged 60 years and older as a single dose [240], regardless of prior history of zoster [241]. Unlike Varivax, a second dose of Zostavax does not boost VZV-specific immunity beyond levels achieved after one dose [242].

The live attenuated varicella vaccine was originally investigated in children with leukemia, in an effort to prevent the development of severe or fatal VZV infection in these patients [243]. Although the varicella and zoster vaccines have significantly changed the impact of VZV infection on healthy pediatric and adult populations, the use of live virus vaccines is in general not recommended for immunocompromised hosts [244], given the potential increased risks for adverse events from the live virus and decreased effectiveness of immunization. Disseminated infection and severe complications after vaccination against VZV have been reported in immunocompromised patients [245–248] and in children with underlying immunodeficiency not apparent at the time of immunization [81,249–253]. However, there are now accumulating data to suggest that live varicella vaccine may be immunogenic and safe in certain immunocompromised pediatric patient populations, including selected HCT recipients [254–256], HIV patients [257–259], and those status post-liver and/or intestine transplantation [260–262]. Guidelines on vaccination of HCT recipients [216,263–265] recommend that live-attenuated varicella vaccine can be considered in HCT recipients who are at least 24 months post-transplant, not receiving immunosuppressive drugs, and free of GVHD. Some also proposed additional immunologic criteria, such as a circulating CD4 cell count of >200 cells/μL, a normal T-cell proliferative response to selected antigens, and/or immunologic response to prior vaccination post HCT [255,256,265].

For Zostavax, a recent retrospective cohort analysis showed that the vaccine administered in the setting of concurrent treatment with biologics was not associated with a short-term increase in the risk for varicella or zoster; instead, a lower risk of zoster (HR 0.61) was observed over a median of 2 years follow-up, compared with unvaccinated controls [266]. Naidus et al. [267] also reported the use of Zostavax in 62 patients with hematologic malignancy, of whom 26 and 5 received an autologous and allogeneic HCT, respectively. A single patient developed zoster during the study period, and there were no documented adverse reactions associated with the vaccine. It should be emphasized that these were select patients without significant immunosuppression. Furthermore, 13 of the 31 HCT patients, who might have been perceived as at higher risk by their clinicians, received concurrent antiviral drugs at the time of vaccination. Larger, prospective, controlled studies to study the safety and efficacy of Zostavax in HCT recipients are needed and its use in HCT populations remains contraindicated [216].

Immunizing healthy household contacts who are not immune to varicella with the varicella vaccine can reduce the risk of household exposure of the HCT recipient to varicella in siblings [268]. The risk of transmission of the vaccine strain is low. After the first 10 years of postmarketing experience, with ~55 million Varivax doses distributed worldwide, there were only three cases of confirmed and two cases of suspected secondary transmission of the Oka VZV [252]. Secondary transmission of the vaccine strain from recipients of Zostavax has not been documented [269]. To our knowledge, no secondary transmission from either Varivax or Zostavax recipients to immunocompromised hosts has been reported to date. Furthermore, illness caused by the vaccine strain in immunocompromised individuals is treatable with acyclovir, whereas infection associated with wild-type VZV can be severe. Since the benefits of vaccination outweigh the potential risk of transmission of vaccine-type virus to immunocompromised persons, routine vaccination of susceptible household contacts of immunocompromised persons is recommended [216,244]. Healthcare workers in contact with HCT patients should also be evaluated for susceptibility to VZV and immunized. There are also no contraindications for eligible household members of immunocompromised persons or healthcare workers in contact with HCT patients to receive the zoster vaccine for the prevention of zoster and PHN. Any vaccine recipients, particularly healthcare workers and household contacts, should avoid contact with a susceptible immunocompromised person if a vaccine-related rash occurs [244]. Since some vaccine recipients become candidates for HCT, post-transplant reactivation of vaccine virus has been demonstrated in a few instances. However, the vaccine virus appears to reactivate less commonly than wild-type VZV [270]. Only two cases of zoster were reported during a 10-year follow-up of ~2000 healthy children vaccinated with Varivax [236]. If symptomatic reactivation occurs, the vaccine virus is susceptible to inhibition by acyclovir and episodes of vaccine-related herpes zoster can be treated with this drug [271].

Whether immunization with an inactivated preparation of the live attenuated varicella vaccine could substitute for the "natural" resensitization caused by VZV reactivation after HCT and whether the early restoration of immunity modified the clinical course of recurrent VZV disease have been evaluated in two prospective studies [32,272]. The administration of the live attenuated varicella vaccine to elderly individuals without underlying disease boosts VZV-specific immunity, and immunization has been evaluated as a strategy to reverse the decline of T-cell responses that is associated with the increased risk for herpes zoster in this population [238,273]. Although live attenuated varicella vaccine is contraindicated in most immunocompromised patient populations, the vaccine can be heat inactivated without loss of immunogenicity [274]. HCT recipients recover VZV immunity but reconstitution is delayed for months and often does not occur until after the patient has experienced herpes zoster [4,32,61,73]. A single-dose regimen of inactivated varicella vaccine induced short-term immunologic enhancement but did not result in clinical benefit. A three-dose regimen in which vaccine was given to allogeneic or autologous transplant recipients at 30, 60, and 90 days after HCT boosted cell-mediated immunity and modified the clinical severity of herpes zoster, but did not reduce the overall incidence of herpes zoster after HCT [272].

When inactivated varicella vaccine was given to autologous HCT recipients in a regimen that included a pretransplantation dose, and also doses given at 30, 60, and 90 days after HCT, the risk of herpes zoster was reduced and protection correlated with reconstitution of VZV CD4 T-cell immunity [32]. In this study, 19 of 58 unvaccinated patients (33%) developed herpes zoster compared with seven of 53 (13%) of vaccine recipients ($p = 0.01$) (Figure 89.9). The difference was 30% compared with 13% ($p = 0.02$) when two patients who developed zoster before transplant were excluded. VZV-specific CD4 T-cell proliferation was significantly higher in vaccinees by 90 days, following three doses of vaccine ($p = 0.04$), and the differences remained significant at 120 days, after four doses ($p = 0.0001$), and at 6 months ($p = 0.004$), and 12 months ($p = 0.02$) (Figure 89.5).

As noted in the section on host response, this prospective study demonstrated that VZV-specific CD4 T-cell proliferation was a correlate of protection against VZV reactivation [32]. The risk of zoster was reduced by 19% per unit increase in stimulation index >1.6, and a stimulation index >5.0 correlated with >93% protection. The relationship between a high stimulation index and reduced risk of herpes zoster could reflect the direct contribution of VZV-specific CD4 T cells to controlling VZV replication, since these cells make IFN-γ and other cytokines, and have cytotoxic function. Reconstitution of VZV-specific CD4 T cells by vaccination may also provide helper functions necessary to expand VZV-specific CD8 T-cell populations that are essential for preserving VZV latency.

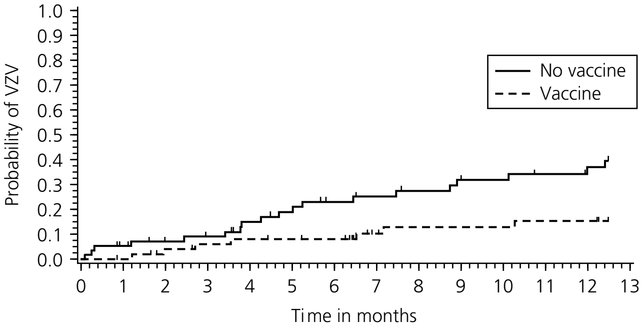

Figure 89.9 Occurrence of zoster in autologous HCT recipients randomized to receive inactivated varicella vaccine or no vaccine. The Kaplan–Meier plot shows the probability of zoster in study participants who were randomized to receive inactivated vaccine (dashed line) and those who were unvaccinated (solid line), from enrollment until 12.5 months after HCT. The incidence of zoster was significantly higher in the unvaccinated group ($p = 0.01$). When the two cases of zoster that occurred before transplant were excluded, the difference remained significant ($p = 0.02$). Source: Hata et al. 2002 [32]. Reproduced with permission of the Massachusetts Medical Society.

In terms of basic immunobiology, the reduced frequency of VZV reactivation observed after active immunization of HCT recipients establishes the critical role of virus-specific T-cell responses in preserving the balance between VZV and the host. Sustaining these host responses by repeated doses is likely to be necessary to preserve clinical efficacy against herpesvirus reactivation while immunosuppressive therapy continues. Immunization of HCT patients against herpesviruses represents a particular challenge because disease is usually due to the reactivation of endogenous viruses during the first several months after transplantation. However, this experience with inactivated varicella vaccine indicates that immunotherapy with vaccines against herpesviruses has the potential to reduce the morbidity caused by these common pathogens after HCT.

A multicenter phase III double-blind, randomized, placebo-controlled trial to study the safety and efficacy of the heat-inactivated varicella vaccine in autologous HCT recipients is in progress (ClinicalTrials.gov Identifier: NCT01229267). Other approaches to the development of VZV vaccines that would be safe in immunocompromised patients are also being pursued. For example, a recombinant VZV glycoprotein E subunit vaccine has been evaluated in a phase I/II clinical trial in healthy individuals. The vaccine was well tolerated and was more immunogenic than a live attenuated VZV vaccine (Varilrix) [275]. The potential benefit of boosting VZV immunity by vaccinating HCT donors before the transplant is also being explored [276]. Whether Zostavax vaccination of HCT donors (HLA-matched siblings) prior to donation can reduce the incidence of zoster in HCT recipients is being evaluated (ClinicalTrials.gov Identifier: NCT01573182).

Conclusion

Primary and recurrent VZV infections remain a serious threat to HCT recipients. Nevertheless, early recognition of the clinical signs of varicella and herpes zoster permits effective intervention with antiviral drugs. Immunization with inactivated varicella vaccine has the potential to reduce the morbidity of VZV reactivation after HCT.

Introduction

Epstein–Barr virus (EBV) is a gammaherpesvirus that is transmitted in saliva (and in cellular blood products with lymphocytes), infecting over 90% of the world's population by adulthood [1–3]. Primary infection is usually asymptomatic, but can present as infectious mononucleosis, especially when infection occurs in adolescence or adulthood. EBV persists for the lifetime of the host as a latent infection harbored by resting B lymphocytes. For most people there are no long-term consequences of infection. In healthy individuals, primary EBV infection and periodic EBV reactivation are met with robust cellular and humoral responses [4].

Patients undergoing hematopoietic cell transplantation (HCT) are at risk for developing EBV-associated lymphoproliferative diseases and lymphomas, collectively termed post-transplantation lymphoproliferative disorder (EBV-PTLD). Aspects of allogeneic (allo)HCT, particularly selective T-cell depletion of the graft or selective pharmacologic induction of T-cell dysfunction aimed at prevention or treatment of graft-versus-host disease (GVHD), have been associated with increased risk of EBV-PTLD. In addition, in some circumstances the use of EBV-naïve donors, human leukocyte antigen (HLA)-mismatched donors, or unrelated donors may also be associated with increased risk. This chapter reviews aspects of EBV biology, EBV-PTLD pathogenesis, diagnosis, treatment, and prevention, and also emerging treatment approaches to EBV-associated malignancies in the setting of HCT.

Aspects of EBV biology

EBV is an enveloped, double-stranded linear DNA virus with a genome length of approximately 180,000 base pairs, including a variable number of terminal repeats useful in determining EBV genome clonality in EBV-associated tumors [1]. EBV infects B lymphocytes, but can infect other cell types, including T lymphocytes and natural killer (NK) cells, and also epithelial and smooth muscle cells [1]. Infection of B cells involves CD21 binding (also known as complement component receptor 2). Linear double-stranded viral DNA is transported to the nucleus where the ends fuse to form a circular plasmid [1]. These plasmids serve as templates for the generation of linear double-stranded DNA concatemers, which are cleaved and packaged into capsids, then enveloped to form virions; or they may serve as templates for plasmid replication. Viral gene expression that gives rise to new virions is referred to as lytic or productive gene expression. Among the viral proteins expressed in lytic infection are the immediate early proteins ZTA and RTA that serve a regulatory role. Immediate early proteins trigger the expression of enzymes involved in replicating virion DNA, such the viral thymidine kinase and the viral DNA polymerase, and also the structural proteins that will ultimately form viral capsids. Among the approximately 80 open reading frames encoded by the virus, most are expressed during lytic infection. However, infection does not always or even usually result in lytic infection. Instead, the viral genome may enter latency. In latency, there is limited viral gene expression. When latency is established in dividing cells, viral plasmid replication is largely a function of the cellular machinery that replicates cellular DNA. The viral origin of plasmid replication is bound by a viral latency protein, Epstein–Barr nuclear antigen 1 (EBNA1), which is necessary for replication of the plasmid by the cellular machinery. Neither the viral thymidine kinase nor the viral DNA polymerase plays any role in this plasmid replication process. EBNA1 is the only viral protein required to maintain the latent genome. In latency, viral plasmids replicate approximately in tandem with the cellular genome during each cell cycle and are partitioned among daughter cells. Some of the genes expressed during latent and lytic infection are shown in Figure 90.1.

In vitro, EBV infects resting B lymphocytes and drives these cells to proliferate continuously in a process termed "immortalization," producing lymphoblastoid cell lines (LCLs). LCLs express six latency nuclear antigens (EBNAs), latency membrane proteins (LMP-1 and -2), and two small but abundant non-coding RNAs (EBER-1 and EBER-2), a pattern of expression termed Latency III or the growth program (Figure 90.2) [1]. In addition, a number of viral microRNAs are expressed [5]. When LCLs are injected into immunodeficient mice, EBV-B-cell lymphoproliferative disease develops [6].

During primary infection in people, there is an initial expansion of latently infected B-lymphocytes driven by the EBV growth program. Proliferation of the initially infected cells leads to expansion of the infected cell compartment, even in the absence of repeated cycles of virion production and new rounds of infection. Whereas in immunodeficient mice this EBV-driven B-cell proliferation is uncontrolled, leading to lymphoproliferative disease, in healthy people the infection elicits NK-cell, $CD4^+$, and $CD8^+$ T-lymphocyte cellular responses that limit the proliferation of infected cells [7,8]. Proliferating B-lymphocytes expressing viral antigens are eliminated. Viral genomes persist as nuclear plasmids

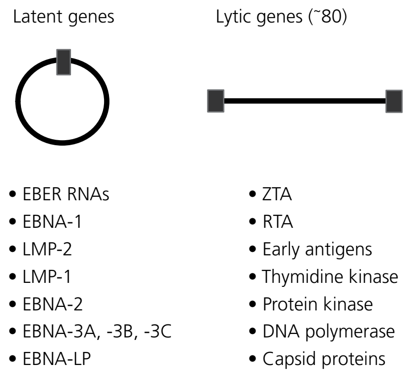

Figure 90.1 Genes expressed during latent and lytic EBV infection. In latent infection, no new virions are produced. Viral DNA is present as a closed circular plasmid. Latent gene expression is limited to non-coding Epstein–Barr virus-encoded RNA (EBER) transcripts, Epstein–Barr virus nuclear antigens (EBNAs), and latency membrane proteins (LMPs). In lytic infection, new virions are being produced. The viral DNA is present in a linear form. Approximately 80 viral proteins are expressed. These include transcriptional regulatory proteins (ZTA, RTA), viral kinases (thymidine kinase and protein kinase) responsible for phosphorylating antiviral nucleoside analogs such as acyclovir or ganciclovir, the viral DNA polymerase, which is necessary for the production of new virion DNA and is inhibited by these antiviral agents, and the structural proteins of the viral capsid.

in a subset of resting memory B-lymphocytes that constitute a lifelong viral reservoir. In these resting cells, there is little or no viral antigen expression. However, intermittent reactivation with virion production results in viral shedding into saliva, tears, and other secretions. In addition, new B-lymphocytes may become infected.

Antiviral drugs, such as acyclovir, ganciclovir, and foscarnet, inhibit the viral DNA polymerase and production of new virions. Phosphorylation of ganciclovir by viral kinases also inhibits cellular DNA polymerases and leads to cell death. These drugs that inhibit the viral DNA polymerase are effective in blocking production of new virions. However, as noted above, new virion production is not required for the spread of viral infection, as latently infected cells that harbor viral plasmids can proliferate. Hence these antiviral agents have no effects on such latently infected cells. The viral DNA polymerase is not required for genome maintenance in latency (and is not expressed in latency). The viral kinases that phosphorylate ganciclovir are not expressed in latently infected cells, hence ganciclovir and its congeners do not interfere with cellular DNA replication or lead to induction of cell death.

EBV-associated diseases

Infectious mononucleosis is the manifestation of primary infection. Present evidence suggests that signs and symptoms of mononucleosis reflect the immune response to viral infection. Oral hairy leukoplakia, a benign EBV-associated lesion that arises on the lateral margins of the tongue, is mainly seen in patients with HIV but can occur in transplant recipients.

A variety of other syndromes and diseases have been linked with EBV. Chronic active EBV (CAEBV) is a condition where the viral association is well established, whereas systemic lupus erythematosus and rheumatoid arthritis are examples where the viral association remains speculative. Among transplant recipients, EBV hepatitis, ulcerative enteritis, encephalitis, hemolytic anemia, and hemophagocytosis have all been reported but the associations are not well established [9–11].

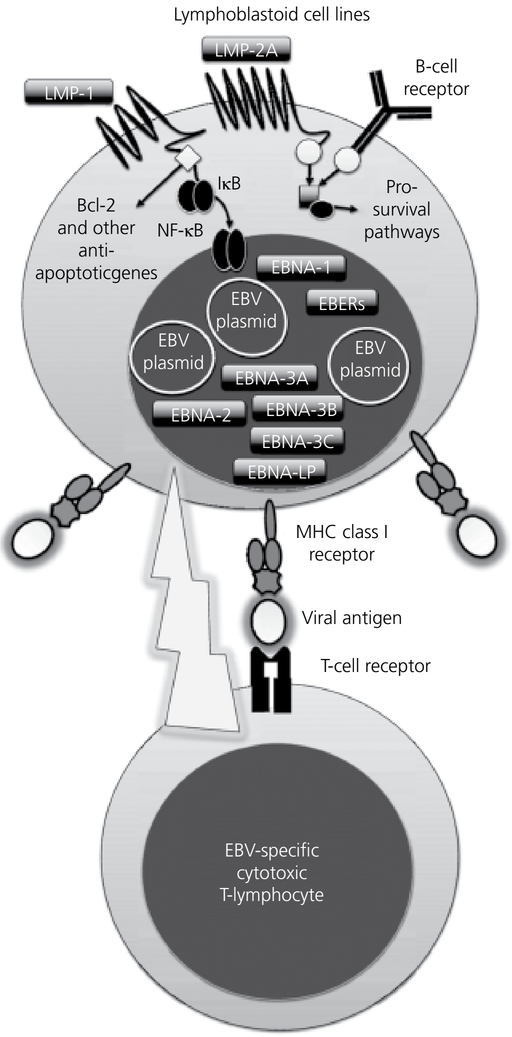

Figure 90.2 Schematic of Epstein–Barr virus latent gene expression by lymphoblastiod cell lines (LCLs). Latent membrane protein (LMP)-1 mimics the tumor necrosis factor receptor CD40 and activates the nuclear factor kappa B (NFκB) signaling pathway, modulating cell proliferation and apoptosis. LMP-2A mimics normal B-cell receptor (BCR) signaling, allowing dysfunctional B cells to escape regulatory checkpoints and survive. Immunodominant antigens are EBNA-3A, -3B, and -3C, which render the cell susceptible to killing by $CD8^+$ cytotoxic T-lymphocytes. Viral antigens are presented to T-lymphocytes on major histocompatibilty complex (MHC) I molecules.

EBV-associated tumors

In the context of tumors, the term “EBV-associated” is generally used to refer to tumors in which viral DNA, RNA, and protein are detected in tumor cells. Endemic Burkitt lymphoma, undifferentiated nasopharyngeal carcinoma, extranodal NK/T-cell lymphoma, and AIDS primary central nervous system lymphomas are consistently associated with EBV tumors [2]. Other malignancies such as Hodgkin lymphoma (HL) are variably associated with EBV. In North America and Western Europe, approximately 20–30% of HLs are EBV associated, whereas in some areas of Latin America and Africa, more than 75% are EBV associated [7,8]. Similarly, in patients with HIV, 90% of HLs are EBV associated. A variety of other T- and B-cell lymphoproliferative diseases, and also about 10% of gastric cancers, are EBV associated [12–14].

Table 90.1 Patterns of EBV latent gene expression

Latency	EBNA-1	LMP-1, -2	EBNA-2, -3A, -3B, -3C, -LP
I	+		
II	+	+	
III	+	+	+

EBNA, Epstein–Barr virus nuclear antigen; LMP, latent membrane protein; -LP, leader protein.

PTLD after solid organ or HCT transplantation is often but not always EBV associated. PTLD has been classified into four subcategories by the World Health Organization: early lesions, polymorphic PTLD, monomorphic PTLD, and classical HL-type PTLD [15]. Early lesions are universally EBV positive and typically arise in the first few months post-HCT, with histology that is akin to a reactive, infectious mononucleosis-like lymphoid expansion or plasmacytic hyperplasia [16]. Polymorphic PTLDs are also always EBV positive and are histologically comprised of a mixture of plasma cells, histiocytes, and activated B cells, or immunoblasts [16–18]. Early lesions and polymorphic PTLD are the most common PTLD histologic subtypes in post-HCT patients. Monomorphic lesions, many of which are EBV positive, resemble aggressive B-cell lymphomas, including diffuse large B-cell lymphoma or Burkitt lymphoma. Rarely, T-cell and NK-cell PTLDs can occur, 20–30% of which are EBV positive [9,19–22]. EBV-negative PTLDs, when they occur, are of the monomorphic subtype. Primary central nervous system lymphomas account for less than 1% of all PTLDs, are nearly always EBV positive, and tend to present with involvement of the brain parenchyma rather than leptomeningeal involvement [23]. HL-type PTLD is virtually all EBV positive, is of the mixed cellularity histology, and typically arises several years after transplantation.

EBV-PTLDs may arise very early in the post-transplant period when cell-mediated immunity is lacking or pharmacologically suppressed. Especially early after transplantation, these are B-cell proliferations with viral latent gene expression similar to that of LCLs, with a latency III pattern [24]. The viral antigens that drive B-cell proliferation are highly immunogenic and their expression speaks to the absence of cytotoxic T-cell control in these patients [25]. Whereas in the most profoundly immunocompromised patients, EBV-driven polyclonal B cell expansion may be sufficient for EBV-PTLD to develop, in other cases, particularly those that arise more than a few weeks after HCT, oligoclonal or monoclonal proliferations are more characteristic findings. Oligoclonal or monoclonal EBV-PTLDs often show more restricted patterns of viral latency gene expression (latency II, or latency I in cases of Burkitt lymphoma EBV-PTLD), and cellular mutations, deletions, or translocations are present in many cases. Patterns of EBV latent gene expression are shown in Table 90.1. Thus EBV-PTLD represents a spectrum of lesions with regard to viral gene expression, clonality, and histologic type.

In the alloHCT setting, EBV-PTLD typically arises in *donor* B-lymphocytes, although lesions of host-cell origin have been described and may be more common in non-myeloablative alloHCT [26–28]. High-dose HCT conditioning destroys the viral B-cell reservoir and, at least in some cases, may eliminate the host virus [29]. EBV-PTLD has also been described in the setting of autologous HCT when the preparative regimen or stem-cell processing procedure has included selective T-cell depletion (as used for the treatment of T-cell malignancies).

Allogeneic HCT and EBV-PTLD risk factors

The incidence of EBV-PTLD following HLA-matched, related donor alloHCT without T-cell depletion of the graft is less than 1% in adults and slightly higher (around 3%) in children [27,30,31]. However, in some series the incidence can be as high as 15–30% [27,30,32]. Commonly recognized risk factors are related to the donor, the preparative regimen, graft manipulation, GVHD prophylaxis, the occurrence of GVHD and its treatment, and the patient.

Rates of EBV-PTLD using unrelated donors has been reported to be higher than with related donors, although on multivariate analysis the risk may be limited to unrelated-donor HCTs that also utilize T-cell-depleted grafts or antithymocyte globulin (ATG) [33–35]. The incidence of EBV-PTLD in patients receiving HLA-mismatched grafts has been reported to be 10–15%, compared with 1% in those receiving HLA-matched grafts [32,35,36]. However, this increased risk with HLA mismatch may only apply to those approaches that also use T-cell depletion and/or ATG; multivariate analyses have shown that patients who receive HLA-mismatched grafts but no selective T-cell depletion or ATG have the same risk for EBV-PTLD as those receiving fully HLA-matched grafts [35].

Umbilical cord blood (UCB) grafts contain mostly naïve T cells that lack virus-specific cytotoxic T-cell activity. In this respect, UCB grafts resemble T-cell-depleted grafts. However, EBV generally does not cross the blood–placenta barrier and therefore the graft does not harbor infected cells. The incidence of EBV-PTLD after UCB HCT varies but may be as high as 5% [28,37–39]. ATG conditioning may increase the risk [28,38,39].

ATG, which is commonly used both in HCT conditioning regimens to promote engraftment and decrease GVHD and in the treatment of GVHD, is associated with an increased incidence of EBV-PTLD [11,28,33,35,39–41]. ATG is commonly used in the treatment of aplastic anemia and prior therapy with ATG has been associated with increased risk for EBV-PTLD after alloHCT, with a cumulative incidence of EBV-PTLD of 4% in those receiving one prior course and 25% in those receiving two prior courses [42]. In the treatment of severe aplastic anemia without alloHCT, ATG has also associated with the development of EBV-associated lymphoproliferative disorders [43,44].

Some approaches to HCT graft manipulation are associated with an increased incidence of EBV-PTLD (10–15%). Especially high rates of EBV-PTLD were seen historically with the use of an immunorosette technique using tetramers of anti-CD2 and anti-CD3 monoclonal antibodies that resulted in selective T-cell depletion [45]. Other approaches are associated with a risk similar to that with unmanipulated grafts (typically less than 1%) [26,27,35,36,40,46]. Depletion of both B and T cells, either by counterflow elutriation or by use of antibodies, results in much lower rates of EBV-PTLD similar to those associated with unmanipulated grafts [45]. Perhaps B-cell depletion, by reducing the number of lymphocytes that harbor EBV, reduces the need for T-cell control. Lending support to this hypothesis is the observation that GVHD prophylaxis with high-dose post-transplantation cyclophosphamide (given post-HCT days 3 and 4) has not yet been associated with EBV-PTLD, even among those receiving conditioning with ATG [47]. In a single-institution series of almost 800 consecutive patients who received high-dose post-transplantation cyclophosphamide as part of their GVHD prophylaxis following HCT, none developed EBV-PTLD [47].

Patients with congenital primary immunodeficiencies, such as X-linked lymphoproliferative disease, Wiskott–Aldrich syndrome, ataxia–telangiectasia, severe combined immunodeficiency, and other T-cell immunodeficiencies, are at high risk for EBV-associated lymphoproliferative disorders before alloHCT. AlloHCT is often the only curative option, although risk for developing recurrent EBV-associated lymphoproliferative disorders post-HCT, including EBV-PTLD, remains high. In a multivariate model adjusting for other risk factors, including selective T-cell depletion of grafts and the use of ATG, patients undergoing HCT for primary immunodeficiencies had a relative risk for EBV-PTLD of 2.5 compared with those receiving HCT for hematologic malignancies [36]. However, the incidence varies greatly as a function or the preparative regimen and details of immunosuppression [48].

CAEBV is a lymphoproliferative disorder first described in Japan, but now recognized to afflict persons worldwide. In patients with CAEBV, primary EBV infection is followed by chronically elevated EBV viral copy number in the blood, with persistent and progressive manifestations including hepatitis, cytopenias, hemophagocytic syndrome, splenomegaly, lymphadenopathy, and pneumonitis [49]. EBV-associated B- or T-cell lymphoproliferation may progress to aggressive lymphoma. AlloHCT is believed to be the only potentially curative treatment, although as with primary immunodeficiencies, these patients are at high risk for EBV lymphoproliferation after HCT [49]. It should be noted that CAEBV is not the same entity as chronic fatigue syndrome. Chronic fatigue syndrome has no generally accepted viral etiology and has a much better prognosis than CAEBV.

EBV-PTLD presentation and diagnosis

The clinical presentation of EBV-PTLD can vary from indolent to aggressive and from localized to disseminated. EBV-PTLD can present as a mononucleosis-like illness with fever, lymphadenopathy, pharyngitis, and malaise. Fulminant disease may be associated with hepatic transaminitis, respiratory compromise, and multi-organ dysfunction. Extranodal involvement may include Waldeyer's ring, the gastrointestinal tract, liver, bone marrow, central nervous system, skin, and lungs [28,41,50]. Central nervous system involvement may be parenchymal or leptomeningeal. Pulmonary involvement may manifest as a diffuse infiltrate or nodules. Definitive diagnosis requires biopsy with EBER in situ hybridization or LMP-1 immunohistochemistry. Whereas EBER RNAs are abundantly expressed across the spectrum of EBV-PTLD, LMP-1 is not expressed in a subset of these tumors.

The first year following HCT is the period of highest risk for EBV-PTLD, presumably reflecting the duration of time to establishment or re-establishment of an EBV-specific cellular response [24,26,51–53]. The median time from HCT to EBV-PTLD varies but many reports indicate peaks between 60 and 150 days post-alloHCT [28,30,32,40,54,55]. GVHD is a risk factor for EBV-PTLD [27,30,33,35,41]. Furthermore, treatment of GVHD with drugs that selectively deplete T cells, such as anti-CD3 monoclonal antibodies, increase the risk [27]. Whereas the risk of EBV-PTLD declines with time and is rare after 1 year, chronic GVHD is associated with prolonged risk over years [35].

EBV monitoring

EBV DNA can be readily detected and quantified in peripheral blood by real-time polymerase chain reaction (RT-PCR). In healthy individuals, EBV DNA is predominantly detected in the lymphocytes, or peripheral blood mononuclear cells (PBMCs), on the order of 1–50 infected cells per million PBMCs [56]. With immunosuppression, the number of infected cells increases [57]. There is also evidence that copy number per infected cell increases, perhaps reflecting increased lytic viral infection [58]. Monitoring EBV DNA in PBMCs may provide a guide to those at highest risk for EBV-PTLD, but some patients with high copy number do not develop any associated disease [59,60]. Therapies that deplete B cells, such as the anti-CD20 monoclonal antibody rituximab, deplete the cells that harbor virus. Hence serial monitoring of EBV DNA in PBMCs in the setting of rituximab treatment almost inevitably shows a decline in PBMC EBV DNA viral copy number, even in the face of progressive EBV-PTLD [57]. Hence monitoring PBMC viral copy number may identify patients at high risk but is of limited value following interventions that involve rituximab and other B-cell-targeted therapies.

EBV DNA is also detected in plasma or serum. Healthy EBV-seropositive adults rarely have detectable cell-free EBV DNA in blood. However, in patients with EBV-associated malignancies, such as undifferentiated nasopharyngeal carcinoma, EBV-positive HL, and extranodal NK/T-cell lymphoma, EBV DNA is usually detected in plasma or serum [61–63]. Prior to treatment, the level of cell-free EBV DNA in plasma has emerged as a useful prognostic marker that complements anatomic staging in nasopharyngeal carcinoma [62]. The cell-free EBV DNA detected in such patients is not virion DNA but viral DNA released from tumor cells. In other settings (acute infectious mononucleosis, HIV infection), virion DNA may be present in serum or plasma [64]. The sources of viral DNA are illustrated in Figure 90.3. As with monitoring in PBMCs, high levels or rising levels of EBV DNA in plasma or serum raise suspicion for an established or evolving EBV-PTLD [40,65].

There are no established, generally accepted guidelines for monitoring EBV DNA in the HCT setting. Some institutions monitor whole blood, others PBMCs, others serum or plasma. Some institutions report values in viral copies per microgram of DNA, while others report viral copies per volume of blood or cell-free blood. Others report "low-level" or "high-level" EBV DNA (with inter-institutional variation in the thresholds for these categories). Some institutions regularly monitor the EBV DNA in post-HCT patients whereas others monitor only in the setting of particular signs or symptoms.

EBV DNA in blood is often used to monitor the response of EBV-PTLD to treatment. Plasma EBV DNA has been shown to be a more reliable measure of treatment response than EBV DNA in PBMCs [60,65]. Rapid change in EBV DNA levels with EBV-PTLD treatment is common, but does not consistently correlate with survival outcomes [55].

Treatment and prevention

EBV-associated non-neoplastic diseases

Acyclovir, ganciclovir, or their congeners interfere with the production of EBV virions and salivary shedding, but randomized controlled studies provided no evidence that the duration of symptoms associated with infectious mononucleosis is affected by such antiviral therapies [66]. These agents are very effective in treating or preventing oral hairy leukoplakia.

EBV-PTLD

Withdrawal or reduction of immunosuppression in the early post-HCT period may not lead to quick rebound of a previously immunosuppressed immune system as sometimes occurs in solid

	EBV DNA assessment by RT-PCR	Comments
Whole blood	Sources of EBV DNA: PBMCs, virions, and DNA shed from latently infected tumor cells	• Whole blood contains all sources of EBV DNA • When whole blood, PBMC, and cell-free quantification are all available, elevated PBMC or whole blood values without elevated plasma values should be interpreted with great caution • Routine monitoring of EBV DNA copy number is only advised in conjunction with HCT procedures with a risk of EBV-PTLD of > 5%. The different limitations of monitoring whole blood, PBMCs, serum, or plasma need to be recognized.
PBMCs	Plasma DNA DNA intended for virions	• Healthy EBV-seropositive individuals have EBV DNA in PBMCs • EBV-PTLD and other EBV(+) tumors harbor plasmid DNA • Treatment with anti-CD20 monoclonal antibody therapy (rituximab) leads to B-cell depletion. This is commonly associated with a decrease in EBV DNA copy number. Such decline may occur even in the setting of tumor progression. Diagnostic or predictive value is limited in such patients. • Values > 10,000,000 copies/million PBMCs are useful in prompting investigation for EBV-PTLD in high-risk settings
Serum or plasma	EBV DNA from latent cells (tumor or benign) EBV DNA encapsidated in virions or shed from lytic cells	• States where cell-free EBV DNA can be detected include EBV(+) tumors, primary EBV infection, and immunocompromise {HIV) • Healthy EBV-seropositive individuals do not have detectable cell-free EBV DNA • Monitoring may be useful even in rituximab-treated patients • Values > 1,000 copies/mL are useful in prompting investigation for EBV-PTLD in high-risk settings

Figure 90.3 Epstein–Barr virus (EBV) copy number quantification by real-time polymerase chain reaction (RT-PCR) and guidelines for interpretation. Whole blood contains EBV DNA in peripheral blood mononuclear cells (PBMCs), cell-free DNA, and potentially virions. PBMCs may contain either latent or lytic EBV DNA. In PBMCs that are latently infected, EBV DNA exists as circular plasmids that rely on cellular polymerases for replication only in tandem with cell cycle. In PBMCs that are lytically infected, EBV DNA is linear and undergoes replication using viral polymerases. Cell-free components of blood are serum or plasma. Cell-free EBV DNA can be shed or extruded from latently infected cells, which can include tumor cells or benign lymphocytes. Cell-free EBV DNA can also be present as encapsidated, infectious virions, or exist as free fragments of EBV DNA shed from dying lytically infected cells.

organ transplant recipients. GVHD may develop or worsen [54]. However, the approach is sometimes effective and is used in conjunction with other treatment strategies in some institutions [38,67]. Reduced immunosuppression may be more effective later in the post-HCT course, when partial immune reconstitution has already occurred [68]. In a large series from the European Group for Blood and Marrow Transplantation center, a lack of reduction of immunosuppression upon PTLD diagnosis was associated with a poor response to rituximab-based therapy and higher mortality [69]. There is growing interest in the antitumor and potential antiviral activities of mammalian target of rapamycin (MTOR) inhibitors, such as sirolimus and everolimus. Although restricted to case reports, PTLD remissions have been reported in solid organ transplant patients who have had their immunosuppressant regimen changed from a calcineurin inhibitor to an MTOR inhibitor, in some cases coupled with rituximab therapy [70,71]. Similarly, Syk tyrosine kinase inhibition may be a future therapeutic strategy in EBV-PTLD, as the EBV latency membrane protein 2 (LMP2) is a B-cell receptor mimic that sends survival signals to EBV-positive PTLD cells through the Syk tyrosine kinase pathway [72].

Rituximab for the treatment of post-HCT EBV-PTLD is often effective and has dramatically changed survival outcomes, where reported mortality rates once approached 100% [27,36]. Rituximab is well tolerated and does not threaten the allogeneic graft as does combination cytotoxic chemotherapy. One systematic review estimated the efficacy for treatment in the HCT setting at 63% [73]. “Incipient” EBV-PTLD, characterized by the development of lymphadenopathy or fever in the setting of a rising EBV DNA viral load, has been treated with rituximab, CTL infusions, or both [74]. In small series, reduction of immunosuppression in combination with rituximab therapy has also been reported [10,55].

Donor lymphocyte infusion (DLI) is often effective in EBV-PTLD [31,42,75]. The major complication of DLI is GVHD [40]. Sometimes very modest DLI doses have proved effective [76]. Note that the effect is generally not a GVH effect, since most cases of EBV-PTLD are donor-cell proliferations. DLI leads to the control of EBV-positive B-lymphocyte proliferation, presumably by targeting viral antigens. In EBV-seropositive healthy persons, a small fraction of T cells have EBV specificity [77]. In some instances, donors who were not the alloHCT stem-cell donors have been used. In these cases, there may be both GVH-related antitumor effects and antiviral effects. DLI for EBV-PTLD is typically combined with rituximab therapy.

Amplification of cellular responses to EBV ex vivo allows a more specific adoptive immunotherapy approach, with less risk of GVHD than with DLI [78]. EBV lymphoblastoid cell lines from normal donor B cells were used as stimulators of cytotoxic T-lymphocyte (CTL) expansion [79]. Responses to a multitude of viral antigens, particularly the immunodominant latency antigens EBNA-3A, -3B and -3C that are commonly expressed in EBV-PTLD, occur following CTL infusion. In the post-HCT setting, gene-marked CTLs have been shown to persist in recipients for years after infusion [80].

Advances in the field have included genetically modified CTLs that proliferate and persist despite concurrent immunosuppression

Table 90.2 Treatment options for EBV-PTLD

Recommended	Rituximab EBV-specific CTL infusion or DLI Standard lymphoma chemotherapy
Limited utility	Reduction of immunosuppression
Not recommended	Anti-herpesvirus agents (e.g. ganciclovir) Treatment based on EBV DNA monitoring without confirmatory biopsy

PTLD, post-transplantation lymphoproliferative disorder; CTL, cytotoxic T-lymphocyte; DLI, donor lymphocyte infusion

or that have a “safety switch” where a drug can be administered to induce CTL suicide should GVHD occur [81–83]. UCB HCT patients have some of the highest rates of viral complications due to the relatively naïve immune system derived from cord blood and a lack of experienced, virus-specific CTLs in the graft. Recent work in adoptive immunotherapy has now extended to UCB transplants, overcoming some barriers that the predominantly naïve UCB-derived T cells posed when trying to expand such cells successfully into virus-specific CTLs [84]. CTLs have now been generated to have EBV-specific cytotoxicity, and also cytotoxicity against other viruses that are problematic in the post-HCT period, such as adenovirus or cytomegalovirus [85,86].

The time required to expand EBV-specific CTLs ex vivo has been a limitation, previously taking several weeks. Current efforts in adoptive immunotherapy have therefore also focused in decreasing the production time of CTLs. Virus-specific CTLs have been produced in a time span of 10 days using a method of donor PBMC stimulation with viral peptides and pro-proliferative cytokines [87]. Patients have been successfully treated with virus-specific CTLs that were isolated in a matter of hours from frozen donor material or third-party donors using HLA multimers and magnetic beads [88]. CTLs have now been isolated from the whole blood of donors and made ready for adoptive immunotherapy in as little as 30 hours using selection methods based on EBNA-1-specific interferon-gamma secretion that do not rely on ex vivo expansion [89].

Cytotoxic chemotherapy is used in the treatment of post-alloHCT EBV-PTLD in patients who fail to respond to antibody and cellular therapies or where cellular therapies are not available. In patients who are able to tolerate combination chemotherapy with rituximab, long-term disease-free survival can be achieved in some [90]. However, chemotherapy is often not well tolerated or patients are too unwell to begin such therapies. Treatment options for EBV-PTLD are listed in Table 90.2.

Preemptive intervention with reduction in immunosuppression, adoptive cellular therapy, antibody therapy, or combinations of these approaches been explored in association with HCT approaches with particularly high incidences of EBV-PTLD. Reduction of immunosuppression may lead to GVHD or graft rejection. However, in a prospective study of pediatric HCT patients who were monitored for EBV in PBMCs and had preemptive reduction of their immunosuppression if EBV copy number crossed the protocol’s threshold, no increase in GVHD was observed among those who had their immunosuppression reduced [59]. Even a single dose of rituximab may be sufficient to prevent EBV-PTLD in patients with rising, very high EBV viral copy numbers [73]. Responses can be quick, with EBV DNA viral copy number falling to zero within 2 weeks of the first rituximab dose [91]. In patients with primary immunodeficiencies, weekly EBV monitoring and preemptive rituximab have been reported to result in reductions in EBV-PTLD-associated morbidity and mortality [54]. In a retrospective study comparing PTLD events pre- and post-implementation of a protocol monitoring EBV and administering preemptive rituximab, the EBV protocol was associated with lower EBV-related mortality and fewer cases of monomorphic PTLD [92]. Adoptive cellular therapies with EBV-activated CTLs have also been used effectively in this setting.

EBV-specific CTLs have been used prophylactically in high-risk patients post-HCT with great success [54,78,93]. Prophylactic EBV-specific CTLs are particularly used in patients receiving HCT for primary immunodeficiencies or CAEBV or in other high-risk groups, such as those receiving T-cell-depleted grafts [49,54,78].

The role of prophylaxis with antiviral drugs such as acyclovir or valganciclovir in preventing EBV-PTLD is uncertain. However, insofar as these agents are routinely used for other reasons and yet EBV-PTLD remains a problem, we know that their efficacy remains limited at best. Prophylactic post-HCT rituximab has been used in high-risk patients, which may decrease the incidence of EBV-PTLD by reducing the burden of EBV-infected B cells, but definitive evaluation of the risks and benefits is still awaited [38].

Treatment of other EBV-associated tumors

The successes in the use of EBV-specific CTLs for the treatment of EBV-PTLD in HCT have stimulated interest in adoptive T-cell therapy for other EBV-associated tumors. With regard to such immunotherapeutic approaches. the tumor cells must present antigens that can be effectively killed by cognate T cells. In EBV-associated HL, major histocompatibility complex (MHC) class I molecules are consistently expressed and HL cells are susceptible to lysis by antigen-specific CTLs. However, much of the HL tumor consists of regulatory T-lymphocytes, which release cytokines and chemokines that disrupt cellular immune responses. Thus, although adequate antigen presentation occurs, dysregulated immune responses can damp the efficacy of EBV-specific CTLs.

The pattern of viral antigen expression varies by tumor type, most of which are more restricted than in EBV-PTLD. The viral latency antigens typically targeted by EBV-specific CTLs expanded in vitro using LCLs, namely EBNA-3A, EBNA-3B, and EBNA-3C, are not expressed in most EBV-associated malignancies. In Burkitt lymphoma, only EBNA-1 is expressed by tumor cells. In HL, EBNA-1 and the latent membrane proteins LMP-1 and LMP-2 are expressed. In EBV-associated nasopharyngeal carcinoma (NPC), the LMPs are less consistently expressed. In EBV-PTLD, there is generally a match between the viral antigens expressed by tumor cells and the antigens targeted by EBV-specific CTLs. In patients with EBV-associated HL or EBV-associated NPC, a more restricted, and often less immunogenic, array of antigens are available as CTL targets. These patients have also been shown to have decreased EBV-specific T cells compared with healthy controls, suggesting that bolstering immune function with CTLs may have antitumor activity. EBV-specific autologous CTL therapy has had some successes in these patients, with demonstration that expansion of CTLs is feasible, even in heavily treated patients [94]. Infusions also appear to be well tolerated and safe, and there is evidence that CTLs are able to home to the tumor site [95]. Some NPC patients treated with autologous CTLs have been able to mount an antitumor, LMP-2-specific immune response with stabilization or regression of refractory tumors [94,96].

Similar results have also been reported with EBV-positive HL, with LMP-2-specific CTLs able to induce remissions in some patients with relapsed HL [95].

Conclusion

EBV is ubiquitous and most adults harbor latent EBV infection in a small percentage of B-lymphocytes. EBV drives the proliferation of infected lymphocytes and, in the setting of impaired cellular immunity post-HCT, EBV-PTLDs can develop. The major risk factors for EBV-PTLD are the use of selectively T-cell-depleted grafts and selective anti-T-cell agents. Monitoring strategies, if used, should be employed with an understanding of the limitations in peripheral blood EBV DNA quantification as a surrogate detection method. The prognosis of patients with EBV-PTLD has improved substantially and currently available treatment options, namely antibody and adoptive cellular therapies, are often effective.

CHAPTER 91

Respiratory Viruses After Hematopoietic Cell Transplantation

Sachiko Seo[1] **and Michael Boeckh**[2]

[1] Department of Hematology and Oncology, National Cancer Research Center East, Chiba, Japan
[2] Fred Hutchinson Cancer Research Center and University of Washington School of Medicine, Seattle, WA, USA

Introduction

Community-acquired respiratory virus infections are an important cause of morbidity and mortality after hematopoietic cell transplantation (HCT) [1–3]. The infection epidemiology in HCT recipients usually parallels that observed in the community, as these viruses circulate in immunocompetent individuals (including healthcare personnel and family members). Respiratory syncytial virus (RSV), influenza viruses, human coronaviruses (HCoVs), human bocavirus (HBoV), and human metapneumovirus (HMPV) have a seasonal distribution, whereas human rhinoviruses (HRhVs) and parainfluenza virus infections often occur year around (Figure 91.1, Table 91.1) [4,5]. The most significant impact on morbidity and mortality after HCT has been from RSV, parainfluenza viruses, HMPV, and influenza viruses as these viruses frequently cause lower respiratory tract disease (LRD), which is associated with high mortality [1,6–11]. LRD may also occur with HRhVs, HCoVs, and HBoV, but the frequency appears to be low [5].

Molecular detection techniques have largely replaced traditional virologic methods [12–16]. One feature of respiratory virus infections is that the clinical signs and symptoms at presentation are not specific. This syndromic nature of illness therefore requires multiplex testing platforms [17–19]. For non-molecular methods in particular, specimen handling is important for maximal diagnostic yield. Nasal wash or swab specimens should be placed on ice or in a refrigerator immediately and transported to the laboratory without delay to allow for specimen set-up within 2–4 hours [20]. Non-molecular methods available for testing include standard viral cultures (results available in several days), shell vial centrifugation cultures using specific monoclonal antibodies (results after 1–3 days), direct fluorescent antibody tests (results after 2 hours), and enzyme immunoassays (results after 2 hours). On tissue sections from lung biopsy or autopsy specimens, virus-specific monoclonal antibody staining, viral cultures, or polymerase chain reaction (PCR) can be used. The role of non-molecular assays is diminishing as PCR- or Luminex-based platforms allow for multiplex testing with short turnaround times [21,22]. Infection control guidelines are not discussed here as they have been reviewed by an international expert panel [23–25].

Respiratory syncytial virus

Clinical significance

RSV is an RNA virus (paramyxovirus) that causes a wide range of respiratory diseases, ranging from life-threatening bronchiolitis in infants and potentially fatal pneumonia in transplant recipients to a mild upper respiratory tract infection (URI) in immunocompetent adults and older children. The virus has also been implicated in a number of respiratory illnesses in immunocompetent or mildly immunosuppressed individuals, such as otitis media, exacerbation of chronic obstructive lung disease, and community-acquired pneumonia in elderly persons. In patients receiving cytotoxic chemotherapy for hematologic malignancies with or without HCT, RSV causes URI [26], which may progress to fatal pneumonia [27]. RSV has also been linked to late airflow obstruction, a debilitating condition of accelerated loss of lung function after HCT [28]. During the respiratory virus season, the incidence may be as high as 10% and both allogeneic and autologous transplant recipients may be infected [1,29,30]. The risk of acquisition continues throughout the post-transplant period (Figure 91.2a) [5,31].

Risk factors

Winter season and male gender are risk factors for acquisition of RSV in HCT recipients [1,32]. URI precedes pneumonia in most patients and approximately 20–50% of patients with RSV URI progress to pneumonia after a median of 7 days [30,33]; however, in 20% of patients with RSV pneumonia, URI is not present or very mild or occurs only concurrently with the onset of pneumonia. Risk factors for progression to LRD are neutropenia, lymphopenia, unrelated donor status, and fungal co-infections [1,33]. Corticosteroids at moderate doses (less than 1mg/kg) appear to have minimal impact on progression in cohort analyses [34]. One study in pediatric HCT recipients indicated that asymptomatic shedding of RSV can occur [35]. Two studies in adult HCT recipients, one of which used weekly PCR-based surveillance, did not detect asymptomatic shedding [12,36]. Among patients with LRD, oxygen requirement at LRD diagnosis and bone marrow as cell source were negative predictors for outcome [6]. RSV RNA is detectable in serum or plasma in patients with LRD and may serve as a marker for disease severity [37,38].

Treatment and prevention

Without treatment, RSV LRD is associated with a high fatality rate in highly immunosuppressed HCT recipients [27]. In a large multivariable analysis, RSV LRD (but not URI) was independently

associated with mortality [39]. However, recovery from RSV LRD without specific treatment has been reported in autograft recipients with multiple myeloma [40]. These differences are likely due to less intense immunosuppressive regimens or other poorly defined innate immune mechanisms. Pulmonary copathogens are commonly detected in patients with RSV LRD [6,33] and require aggressive treatment. No adequately powered controlled trials exist for the treatment of RSV infection and LRD in the HCT setting. Available evidence comes from cohort studies and small randomized trials [6,33,41]. The data suggest that treatment of early pneumonia (i.e. prior to oxygen requirement or mechanical ventilation) is associated with improved outcomes (Figure 91.3). This is supported by a recent multivariate analysis that showed that patients who require oxygen at the time of LRD diagnosis have a significantly higher mortality [6]. Intermittent short-duration (2g over 2 hours three times per day) or continuous aerosolized ribavirin is considered the treatment of choice for RSV LRD [3,33]. A small randomized trial recently showed that intermittent aerosolized ribavirin is more effective than continuous administration to prevent progression to LRD [42]. With the use of aerosolized ribavirin, the 30-day all-cause mortality is approximately 30–40% [6]; however, better outcomes have been reported in patients with good prognostic factors at the time of diagnosis. Systemic ribavirin alone does not seem to be effective for the treatment of pneumonia [3,43,44], although the small sample size of available studies prevents the analysis of smaller effects of systemic treatment. Better response rates are reported for systemic treatment of RSV URI; however, small sample sizes limit the strength of the data [3,45].

The role of concomitant intravenous immunoglobulin, RSV-specific immunoglobulin, or palivizumab, an RSV-specific monoclonal antibody directed at the F protein of RSV, is not well supported. A recent multivariate analysis of 82 patients with RSV LRD who were treated with aerosolized ribavirin did not show a benefit of palivizumab or pooled immunoglobulin (Figure 91.4) [6]. Although this is the largest

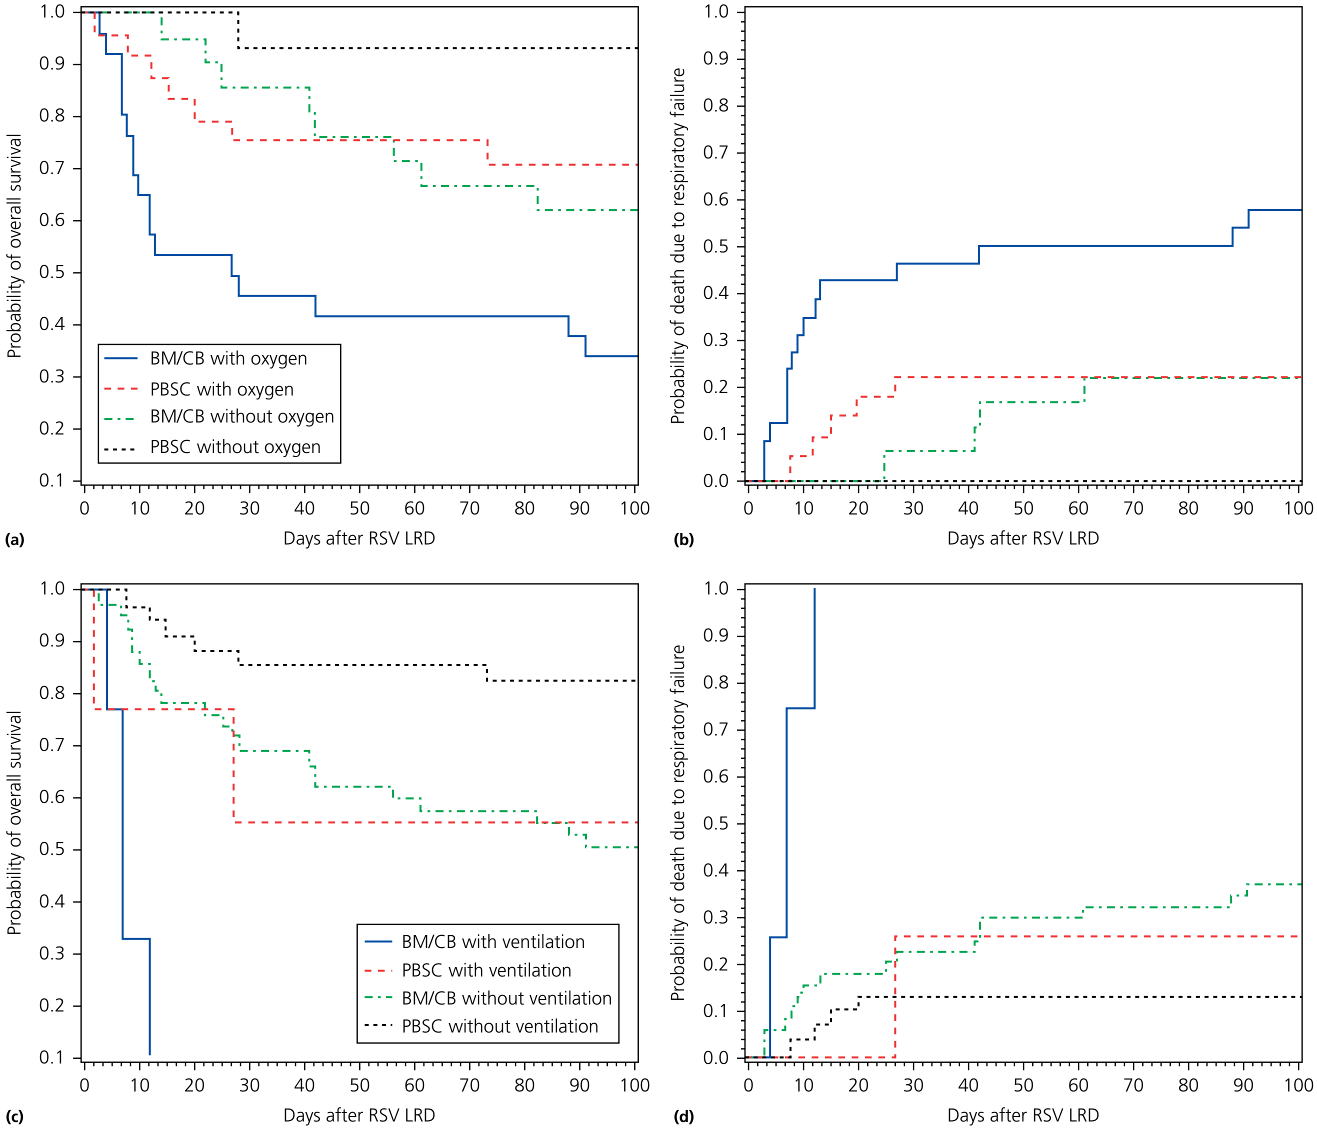

Figure 91.3 Outcomes after RSV LRD by cell source and oxygen requirement or mechanical ventilation. Source: Seo et al. 2013 [6]. Reproduced with permission of Elsevier.

outcome analysis to date, the sample size was not large enough to detect smaller effects. This is consistent with other small reports [3,46,47].

There are several factors that may account for differences in outcome in the available cohort studies. The most important factor seems to be the timing of initiation of therapy. Several studies suggest that treatment that is started when acute lung injury was already present was less successful [6]. Another factor that appears to be important is the stem-cell source. RSV LRD in recipients of peripheral blood stem cells (PBSCs) has a significantly better response to treatment than marrow transplant recipients [6]. Overall, survival of patients with RSV LRD is >90% in PBSC transplant recipients who do not require oxygen at the time of diagnosis (Figure 91.3). Moderate doses of corticosteroids (up to 1mg/kg) do not appear to be associated with poorer outcome in patients with LRD [6], hence reduction of steroid doses may not be required.

Owing to the high mortality of RSV LRD, much interest has focused on prevention and early treatment. Possible strategies are similar to those employed for the prevention of cytomegalovirus (CMV) disease. Although it is well established that RSV URI precedes pneumonia in most cases [33], limited information is available on the extent of asymptomatic shedding of respiratory viruses in HCT recipients [12,35,36]. A small controlled study of preemptive antiviral therapy based on RSV URI showed a decline in viral load but no significant difference in RSV pneumonia; the study was prematurely stopped owing to slow accrual [41]. A recent review of the literature with a pooled analysis suggests a beneficial effect of preemptive ribavirin [3]. Lymphopenia and other factors have been identified as risk factors for progression to LRD and an immunodeficiency scoring index has been suggested [33,34,48]. Hence a more targeted strategy would be to treat only patients who are at higher risk for progression. Some centers have adopted such a strategy, even though randomized trials have not been conducted. Whether palivizumab given preemptively to patients with RSV URI prevents progression to pneumonia has not been studied in a randomized fashion. Evidence ratings in recent American Society for Blood and Marrow Transplantation (ASBMT) and European

Conference on Infections in Leukaemia (ECIL) guidelines are shown in Table 91.2 [24,49].

Prophylactic measures recommended throughout the respiratory virus season include isolation of infected patients, hand washing prior to every patient contact, educational efforts targeted at healthcare personnel and family members, and avoiding patient contact of healthcare personnel and family members with uncontrolled secretions [50]. Whether pharmacologic prophylaxis (e.g., palivizumab, RSV-Ig) throughout the respiratory virus season is effective in preventing infection and disease in HCT recipients has not been studied. Some centers give monthly palivizumab to small children (aged <4 years) undergoing HCT while RSV is circulating in the community, similarly to prevention strategies employed in other children at high risk for RSV bronchiolitis [51].

In patients who acquire RSV before transplant, HCT is generally postponed until resolution of symptoms and cessation of viral shedding, especially when a myeloablative allogeneic HCT is planned. Both ASBMT and ECIL guidelines suggest postponing transplantation in all patients with URI symptoms [24,49]. This approach is supported by a study of pre-transplant RSV infection, which showed rapid progression to RSV pneumonia and high mortality after HCT in patients whose transplant procedure was not postponed [52]. However, there is some evidence that low-risk autologous transplant patients may be transplanted without adverse outcome [53]. Also, outcome of respiratory virus infections appears to be less severe with non-myeloablative or reduced-toxicity conditioning regimens [32].

The management of patients with pre-transplant respiratory virus infections who have persistent low-level viral shedding and subsequently undergo high-risk transplant procedures that cannot be further delayed is poorly defined. Options include close monitoring by PCR, the use of secondary prophylaxis (i.e., RSV-Ig, palivizumab), or continued treatment with systemic ribavirin. Some pediatric HCT programs use antibody preparations in these situations while oral ribavirin has been used for adults. However, no systematic evaluations of these approaches have been performed and the strength of the evidence is at the expert opinion level (CIII) [49].

Table 91.2 Overview of antiviral agents and antibody preparations against respiratory viral infections after HCT

Virus	Drugs	Clinical use in HCT recipients[a]	Strength of evidence[b]	Comments
RSV	Ribavirin	RSV LRD Preemptive therapy for URI	*A-II* B-II	Monoclonal antibody was not effective in a recent cohort study [6]
	RSV-specific immunoglobulin	Combination therapy for RSV LRD	B-III	
	RSV-specific monoclonal antibodies (palivizumab)	Combination therapy for RSV LRD	B-III (*C-II*)	
	Pooled immunoglobulin	Combination therapy for RSV LRD	B-II	
Metapneumovirus	Ribavirin	HMPV LRD	C-III	No apparent effect for pneumonia
Parainfluenza virus	Ribavirin	Parainfluenza virus LRD	B-III	Preemptive therapy has not been tested
	Pooled immunoglobulin	Combination therapy for parainfluenza virus LRD	B-III	
	DAS181	Parainfluenza virus infection	Experimental use	No licensed drugs
Influenza virus	Neuraminidase inhibitors (oseltamivir, zanamivir)	Influenza URI Influenza LRD Prophylaxis Combination therapy	B-II (*A-II)* B-II (*A-II)* A-II *C-III*	M2 inhibitors are only effective against influenza A Prophylaxis is recommended only during outbreaks in patients <6 months after HCT
	M2 Inhibitors (amantidine, rimantidine)	Used in combination with neuraminidase inhibitors and ribavirin	*C-III*	
	Ribavirin	Used in combination with neuraminidase inhibitors and M2 inhibitors	*C-III*	
Rhinovirus	Capsid-binding agents (vapendavir)	No data in HCT recipients	Experimental use	Drug is not FDA approved
Coronavirus	Ribavirin Interferon Corticosteroid Protease inhibitors	No data in HCT recipients	Experimental use	Combination therapy has been used in serious SARS cases
Bocavirus	No drug available			
WU/KI Polyomavirus	No drug available			
Measles Virus	Pooled immunoglobulin	Prophylaxis after exposure to a measles case	*C-III*	Vaccination is common.

Human metapneumovirus

Clinical significance

Human metapneumovirus (HMPV) is a negative-sense non-segmented RNA paramyxovirus [54]. HMPV has two genetic groups, A and B, and each group has two more subgroups, A1, A2, B1, and B2 [54–57]. By age 5 years, virtually all children are seropositive. The virus can cause URI and LRD during the winter season [58,59]. Generally, healthy adults with HMPV infection are asymptomatic or have slight upper URI symptoms [60]; however, serious LRD associated with HMPV has been reported in immunocompromised patients [61–63]. HMPV infection occurs in approximately 5% of HCT recipients (Figure 91.2a) [5]. HMPV disease in HCT recipients immediately post-transplant typically presents with several respiratory symptoms, including fever, nasal congestion, and cough. Once pneumonia develops, rapidly progressive pulmonary infiltrates are frequently accompanied by hypotension, septic shock, or both [61]. Radiographic findings consist of a mixed pattern: small multiple nodules and ground-glass opacities are frequently observed [9,64]. Patients with centrilobular nodules were associated with mild symptoms in one study [9]. Histological assessment showed that diffuse alveolar damage with hyaline membrane formation, foci of bronchiolitis obliterans organizing pneumonia, and diffuse alveolar hemorrhage are common [61].

Risk factors

The progression rate to LRD is poorly defined. Small studies suggest that it may occur in 20–40% of patients with URI (Table 91.1) [65,66]. Among HCT recipients undergoing bronchoalveolar lavage (BAL) for work-up of clinical and radiographic pneumonia, 3–4% had HMPV detected [61]. Most of these patients were previously classified as having idiopathic pneumonia syndrome [61]. Whether asymptomatic shedding occurs is controversial [12,67].

Prevention and treatment

There is no proven treatment for HMPV disease, which may be fatal in HCT recipients [61]. Although intravenous immunoglobulin (IVIg) has been shown to neutralize HMPV effectively in vitro, there are no human studies of its efficacy in vivo [68]. The role of corticosteroids is also not defined. Ribavirin has been shown to have in vitro antiviral activity against HMPV [68] and some case reports supported its use [69,70]. However, clinical data from a non-randomized retrospective analysis suggest no major therapeutic effect of aerosolized ribavirin [9].

Parainfluenza viruses

Clinical significance

Parainfluenza virus, an enveloped paramyxovirus containing single-stranded RNA, is classified into four serotypes. Of the four types of parainfluenza viruses, parainfluenza virus 3 is most common (~80%), followed by serotypes 1, 2, and 4. The incubation time is 1–4 days. Parainfluenza virus infections remain detectable throughout the summer season (Figure 91.1a) [4]. The incidence may be 1–9 % during HCT (Figure 91.2a) [7,71–73]. The main radiographic findings are multiple small nodules in a peribronchial distribution [74].

Risk factors

Virus acquisition is a dependent on exposure to infected persons. However, higher infection rates have also been described in recipients of unrelated or mismatched related donors, with reduced-intensity conditioning regimens, or with acute or chronic graft-versus-host disease (GVHD) [7,71]. T-cell-depleted patients have been reported to have an increased risk of all respiratory virus infections, including parainfluenza virus infections [75].

Similarly to RSV, URI is the predominant presentation. Progression to LRD seems to be less common than with RSV

(Table 91.1) [30]. Late airflow obstruction has been linked to parainfluenza virus URI and LRD [28]. The most important risk factor for progression from URI to LRD is lymphopenia [32,76]. Recipients of non-myeloablative conditioning appear to have a small risk of progression during the first 3 months after HCT [32]. Parainfluenza virus 3 pneumonia is often associated with serious pulmonary copathogens such as *Aspergillus fumigatus* [71]. Pulmonary copathogen was another important factor for the progression in a cohort including non-transplant patients [8]. Male gender, mismatched related or unrelated donor, cord blood transplantation, neutropenia, and chronic GVHD are also associated with a high incidence of LRD [7,8]. Parainfluenza virus 3 pneumonia may also occur after autologous transplantation, mainly in the setting of CD34 selection or use of high-dose steroids [71]. Factors associated with poor outcome after pneumonia include low monocyte counts and high-dose steroid use for pneumonia [76]. Aggressive diagnostic work-up (e.g. BAL) and therapy are indicated in patients with suspected parainfluenza virus pneumonia. In a large retrospective analysis conducted in the 1990s, both URI and LRD due to parainfluenza virus 3 were associated with overall mortality in multivariate models [71].

Treatment and prevention

Mortality of pneumonia is approximately 20–50% [7,71,73,76,77]. Randomized treatment studies have not been performed. In a recent retrospective analysis that employed multivariate models, neither aerosolized ribavirin nor intravenous immunoglobulin led to improved outcome of pneumonia [8,76]. Systemic ribavirin has only been reported in case reports or small series [78,79]. Whether earlier antiviral treatment (e.g. preemptive treatment for URI) is effective in the prevention of pneumonia or late airflow obstruction is unknown [8,78]. The association of high-dose steroid treatment with progression to LRD or mortality might suggest that reduction of immunosuppression may be useful [8,71,76]. The effect of steroids has not been seen in all studies and such an approach has not been tested.

DAS181, a sialidase fusion protein, was developed for treatment of influenza and is also active against parainfluenza viruses [74,80]. Inhaled DAS181 was used in only a few cases after HCT; improvement of symptoms and decrease of viral load were detected [81,82]. BCX2798 is a novel hemagglutinin–neuraminidase inhibitor and showed a protective effect for parainfluenza virus 1 in animal models [83].

Infection control is the mainstay of prevention strategies. Unfortunately, current infection control practices seem to be far from perfect in keeping parainfluenza viruses out of HCT units, as indicated by the high incidence. Parainfluenza virus has been notorious as a cause of persistent outbreaks in HCT units [79,84–87]. Possible explanations for the difficulty in preventing parainfluenza virus from entering HCT units include lack of a vaccine for healthcare workers and close contacts, very mild or lack of symptoms in immunocompetent individuals with prolonged shedding, prolonged asymptomatic shedding in infected patients, and persistence of the virus on environmental surfaces [12].

Influenza viruses

Clinical significance

Influenza viruses belong to the family of orthomyxovirus and are enveloped, single-stranded, pleomorphic RNA viruses. Influenza is classified into three major types, of which type A is most common, followed by type B [88–90]. Influenza type C is uncommon even in the immunocompetent population; there are no reports of influenza C in HCT recipients. Influenza virus infections seem to be less common than RSV and parainfluenza virus infections (Figure 91.2a). Seasonal variations of antigenic and susceptibility patterns are a typical feature of influenza viruses. Studies conducted during the H1N1 pandemic outbreak in 2009 suggested that the 2009 H1N1 strain led to higher rates of LRD, hypoxemia, and prolonged viral shedding [11].

Risk factors

Acquisition of influenza is increased in patients with high-risk underlying disease [39]. Progression to severe LRD is similar to RSV and parainfluenza virus (Table 91.2) [90], and risk factors for progression are age, lymphopenia, and lack of antiviral therapy [10,11,91,92]. In contrast to parainfluenza virus infection where corticosteroids may increase the risk of progression [71], LRD appears to be less common and severe in patients with influenza infection who received corticosteroids (≥1mg/kg) for GVHD [11]. Also, non-myeloablative transplant recipients appear to be less likely to develop LRD [32]. Interestingly, the clinical presentation in HCT often lacks myalgia and high fever which are commonly seen in immunocompetent individuals (Figure 91.5) [12]. Influenza RNA detection in plasma or serum is associated with higher mortality in patients with LRD [93].

Treatment and prevention

Effective prevention is available for influenza, which may explain the lower incidence. Healthcare personnel, family members, and visitors are advised to be vaccinated against influenza early in the season [94]. Antiviral therapy is available for influenza virus infection. owing to the recent emergence of resistance against the M2 inhibitors amantidine and rimantidine (which have a more favorable side-effect profile), these agents should not be used to treat influenza A [95–97]. Neuraminidase inhibitors (e.g. zanamavir, oseltamivir) are active against influenza A and B [98,99]. The treatment duration is recommended as 10 days since prolonged viral detection frequently occurs in HCT recipients [94,96]. Uncontrolled studies suggest that preemptive therapy with neuraminidase inhibitors may be effective in preventing progression to LRD [11,92,100]. Whether higher doses of neuraminidase should be used in severe cases of influenza disease is not well defined [96]. Some centers prefer higher doses owing to uncertain absorption and overall poor outcome; however, the strength of the evidence is low (expert opinion, CIII).

Oseltamivir-resistant strains (mainly H275Y mutation) have emerged in pandemic 2009 H1N1 and also seasonal H1N1 [101–103]. This mutation was detected in 24% of HCT recipients with prolonged virus shedding [103]. Combination therapy with oseltamivir, amantadine, and ribavirin is safe and offers potential for improved treatment efficacy in immunocompromised patients [104]. A novel neuraminidase inhibitor, peramivir, showed early improvement of symptoms and non-inferiority to oseltamivir [105,106]. Two HCT recipients with oseltamivir treatment failure were successfully treated with peramivir [107,108]. Intravenous zanamivir is also another option for oseltamivir-resistant cases. The efficacy was reported in some reports and an early switch from oseltamivir to zanamivir may result in better outcomes [100,109–111]. DAS181 and laninamivir are investigational drugs and a phase II study has reported the efficacy of these drugs for influenza [112,113]. Nitazoxanide is a new class of anti-influenza drug and is

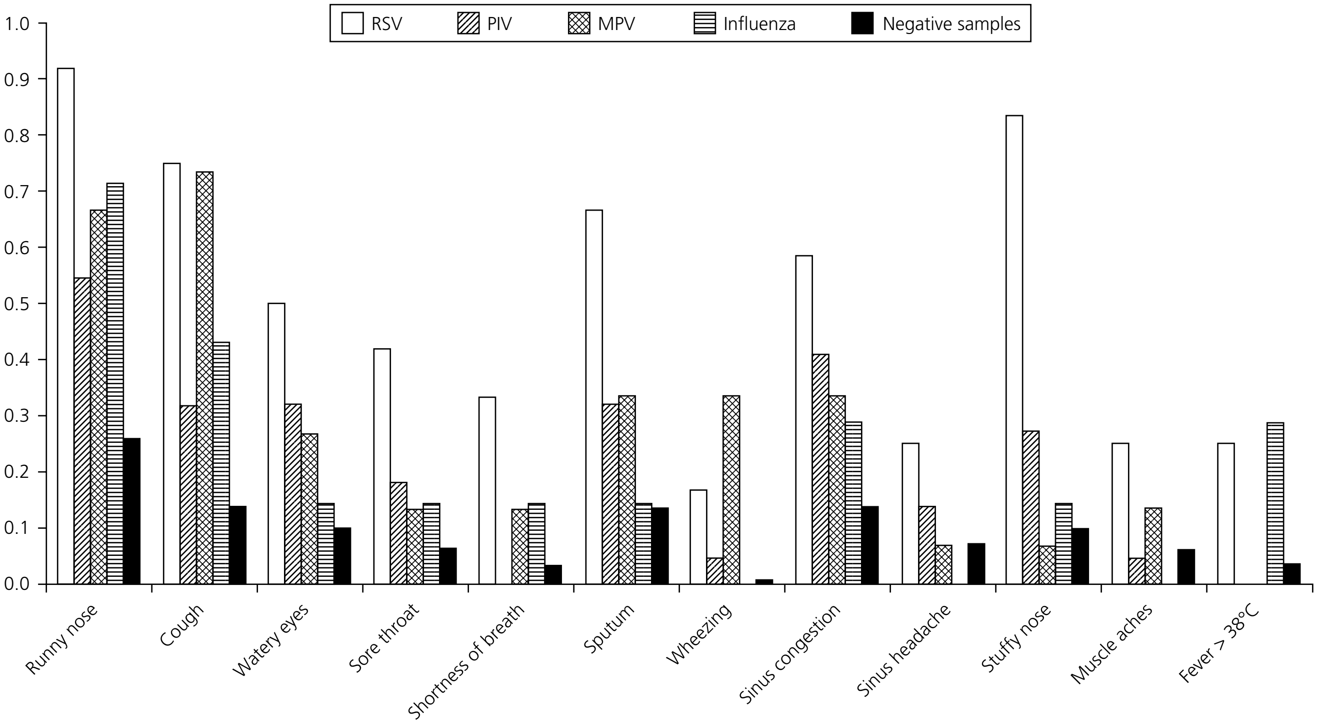

Figure 91.5 Symptoms associated with respiratory virus infection after HCT. Source: Peck et al. 2007 [12].

already approved by the US Food and Drug Administration (FDA) for the treatment of parasites. The anti-influenza mechanism is the inhibition of maturation and intracellular transport of the viral hemagglutinin protein [114]. Nitazoxanide has shown efficacy for the strains that are resistant to currently approved anti-influenza drugs and synergy with neuraminidase inhibitors [115]. A phase III trial to evaluate the efficacy and safety of nitazoxanide with or without oseltamivir is ongoing. The use of hydroxymethylglutaryl coenzyme A reductase inhibitors (statins) as lipid-lowering agents has been associated with reduced mortality from influenza among the general population [116]; no data exist for immunocompromised patients.

Widespread chemoprophylaxis of susceptible immunosuppressed patients in outbreak situations has been recommended [23] and two studies using oseltamivir for prophylaxis suggest that this approach may be safe and effective [117,118].

Vaccination is generally recommended 6 months after HCT [94,119] and single-dose vaccination seems sufficient even after HCT [120,121].

A recent randomized study showed that pretransplant recipient vaccination improved the influenza-specific IgG levels [122].

Human rhinoviruses

Clinical significance

HRhV is classified as a picornavirus characterized by small, naked, single-stranded RNA. There are three groups (HRhV-A, -B, and -C) and approximately 100 serotypes that usually cause mild upper respiratory tract symptoms in immunocompetent hosts. HRhV-C has been reported to cause more severe disease in immunocompetent individuals than HRhV-A and -B [123,124]; however, no data exist for HCT recipients on viral strains and disease severity [125,126]. Using culture techniques, HRhV is infrequently reported as a cause of respiratory infection in HCT recipients. With the widespread use of reverse transcription PCR-based techniques, it is now the most common respiratory virus after HCT (Figure 91.2a) [5]. In a large prospective study, 13% of the HCT recipients had HRhV infection without symptoms and prolonged viral shedding (more than 3 weeks) was very common (Figure 91.6) [5]. Although HRhV is frequently detected in upper respiratory tract illness, some evidence suggests that it may also be a significant cause of LRD [127–129] and that pretransplant infection may lead to adverse outcomes [52]. Exact data on the rate of progression are lacking. Earlier reports showed conflicting results regarding HRhV ability to cause LRD after HCT [128,130]. However, several case reports and a recent initial analysis of a larger cohort showed similar outcomes to those reported with RSV, influenza, and parainfluenza viruses, independent of copathogens [17,127,129].

Risk factors

Factors associated with progression from URI to LRD or mortality have not been defined.

Treatment and prevention

There is currently no licensed drug or vaccine available for the treatment or prevention of HRhV infections. A capsid-binding agent, pleconaril, showed mild reduction of the duration and severity of symptoms and of viral load among healthy individuals, although the drug is not approved as a result of adverse effects and drug interactions [131–133]. BTA-798 (vapendavir), another capsid-binding agent, was evaluated in phase II clinical trials and significant reduction of symptoms was achieved in high-risk patients. Rupintrivir, an inhibitor of HRhV replication, failed to show significant effects in naturally infected patients [134].

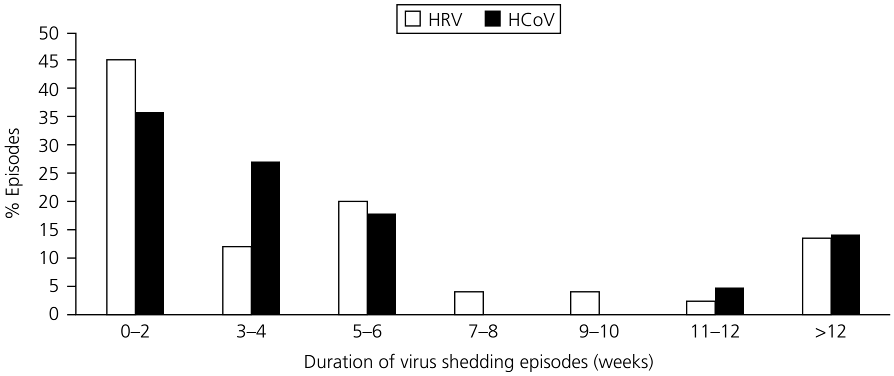

Figure 91.6 Duration of rhinovirus (white) and coronavirus (black) shedding. Source: Milano et al. 2010 [5].

Human coronaviruses

Clinical significance

HCoV is an RNA virus that can cause URI, croup, wheezing, and pneumonia in immunocompetent individuals. Fairly recently, four new strains were described, SARS-CoV (identified in 2003), NL63 (2004), HKU1 (2005), and EMC (2012), in addition to the previously described OC43 and 229E strains [135,136]. Among 823 patients admitted to hospital, 5.7% had HCoV detected; HCoV infection occurred in 8.8% of immunocompromised patients compared with 4.5% of immunocompetent patients [136]. Fourteen of the 47 HCoV-infected patients (30%), including three HCT recipients, were also infected with other pathogens (RSV and *Aspergillus*; influenza A; RSV and HRhV), and these patients had more severe diseases [137]. In the HCT setting, HCoV is the second most common respiratory virus with a day 100 cumulative incidence of 11% (Figure 91.2a) [5]. In a prospective surveillance study, asymptomatic shedding was as high as 41% and the median duration of viral shedding was 4 weeks (Figure 91.6) [5]. Only a few cases of HCoV LRD after HCT have been reported [138–141] and the significance of HCoV as a lower respiratory tract pathogen remains poorly defined in HCT recipients. Prospective studies in immunocompetent hospitalized patients showed that 5.4% of BAL samples were HCoV positive [142]. HCoV infections have also been associated with long-term decline in FEV1 in lung transplant recipients [143]; however, no data exist for HCT recipients.

Risk factors

Factors associated with progression from URI to LRD or mortality have not been well defined.

Treatment and prevention

There are no specific treatments for HCoV. The clinical experiences with severe acute respiratory syndrome (SARS) suggest that ribavirin, interferon, or hydrocortisone may improve outcome, especially when used in combination [144–148]. Protease inhibitors (lopinavir/ritonavir) were also used with ribavirin and showed improved outcome in SARS patients compared with historical controls [149].

Human bocavirus

Clinical significance

HBoV is a human parvovirus originally identified by a random PCR amplification/cloning technique from hospitalized children in Sweden [150]. HBoV is divided into four species [151]; HBoV1 is mainly detected in the respiratory tract and HBoV2–HBoV4 in stool. HBoV has been detected worldwide [152–154] and appears to be common in young children [151]. Symptoms associated with HBoV infections include rhinorrhea, cough, fever, wheezing, hypoxia, and diarrhea. HBoV infection was detected in 2.6% of HCT recipients (Figure 91.2a). A recent prospective study showed that HBoV was commonly detected in pediatric cancer patients with LRD [155]. However, since HBoV is frequently detected with other viruses [156], there is uncertainty as to whether HBoV is a pathogen.

Risk factors

High viral load in nasopharyngeal aspirates and blood samples was suggested to be related to LRD in immunocompetent children [156]. To date, there is no information on the risk factors of HBoV infection in immunocompromised patients.

Treatment and prevention

No antiviral agents exist for HBoV. Corticosteroids were not effective in improving symptoms and the duration of hospitalization among immunocompetent children with HBoV infections [157].

WU and KI polyomaviruses

Clinical significance

Human polyomaviruses, WU (WUPyV) and KI (KIPyV), were described in 2007 and frequently detected in respiratory specimens [158,159]. Infection by WUPyV and KIPyV generally occurs by age 5 years [160]. The prevalence in healthy children was 2–3% for WUPyV and 0.5–3% for KIPyV [161,162]. Incidence rates are similar between patients with and without respiratory symptoms [163–166]. Among HCT recipients, the 1-year cumulative incidence of WUPyV and KIPyV was 8 and 26%, respectively (Figure 91.2b) [167]. Seasonality was not detected [167]. Sputum production in KIPyV and wheezing in WUPyV are distinctive symptoms in HCT recipients [167]. Viral load for KIPyV was higher in immunocompromised patients than healthy children, whereas viral load for WUPyV was similar regardless of immune level [161]. The significance of WUPyV and KIPyV as a cause of LRD in HCT recipients is uncertain.

Risk factors

An important risk factor for acquisition in HCT recipients is age <20 years [167]. HCT patients who acquired KIPyV were more likely to have had another respiratory virus infection in the preceding 2 weeks [167].

Treatment and prevention

No treatments are available for WUPyV and KIPyV.

Measles virus

Clinical significance

Measles virus (rubeola), a paramyxovirus, is a recognized cause of giant-cell pneumonia, developing with and without rash, and severe central nervous system (CNS) disease in immunocompromised hosts, including HCT recipients [168–171]. The incidence of measles is extremely low at most centers owing to the widespread use of measles immunization. In 1997, an outbreak among HCT recipients in Brazil was reported. Among the 122 susceptible patients, severe clinical diseases occurred in one patient and mild symptoms were reported in seven patients [172]. Exanthema was present in all these patients, although it was often atypical. Koplik spots could be observed in five patients. All but one patient had fever and non-productive cough [172]. Recently, outbreaks of measles have been increasing owing to low vaccine coverage [173–175] and HCT recipients may be at increased risk of acquisition.

Risk factors

The key risk factor for acquisition is exposure to an infected individual in the setting of poor vaccine coverage or waning vaccine immunity. In a European study, 80–90% of measles cases were unvaccinated [175]. Risk factors for clinical disease outcome have not been described.

Treatment and prevention

The use of ribavirin has been reported for measles in two critically ill immunocompromised patients; however, no systematic assessment of this intervention can be made [176]. Assuring that all patient contacts have protective antibody titers (either by natural infection or vaccination) is the most important preventive measure. Immunity to measles continuously diminishes after HCT, thereby increasing the risk of acquisition [177–179]. Therefore, the use of vaccine after HCT is recommended after systemic immunosuppression has been discontinued [23]. At a median of 2.4 years after HCT, 49% of the HCT recipients responded to the vaccine [180]. Immunoglobulins may be used after an exposure [181].

Conclusions and future perspective

The increasing use of multiplex molecular diagnostic platforms has significantly increased our knowledge of the incidence, risk factors, and significance of respiratory viral infections after HCT [17]. However, important questions remain. Although many studies analyzed the outcomes and risk factors for LRD by respiratory viruses, the definition of LRD differs between studies. The strictest definition consists of LRD symptoms, positive radiography. and viral detection in the lung, while LRD symptoms plus a positive nasopharyngeal sample are frequently defined as LRD. Thus the current LRD includes a different and broad range of the diseases, which makes comparison of outcome results between centers difficult to interpret. Definitions of diagnostic criteria based on outcome studies should be established [76].

Molecular diagnosis is now used at many centers. At the same time, many open questions remain regarding the significance of some viruses that are now easily detectable and highly prevalent. For instance, studies are needed to define risk factors for progression to LRD for HMPV, HRhV and HCoV. Also, the significance of HBoV remains poorly defined. Molecular diagnostic methods have also provided accurate quantification of viral load [76]. High viral load tends to correlate with poor outcome; however, sufficient data to apply viral load testing to clinical practice are not available. Viral detection and high viral load in blood can be also a marker for severity of respiratory viral infections. Compared with an interventional procedure (e.g. bronchoscopy), blood testing would be more acceptable to HCT recipients; more prospective studies are needed to define the timing of viremia and the optimal blood component (plasma versus cells). Also, further prospective studies comparing viral load in respiratory secretions and blood with outcome are warranted. Once respiratory viral infection progresses to LRD, mortality rates are still high. Although some clinical risk factors have been identified (e.g. lymphopenia), disease progression can occur in patients without these factors. Therefore, research on biomarkers for progression to LRD is needed.

Only a few randomized treatment trials exist for RSV in the HCT setting. Randomized trials are the optimal way to evaluate novel interventions and are feasible for the treatment of RSV URI. However, such trials may be difficult or impossible to conduct for LRD owing to the low frequency of this event. The RSV LRD outcome study by Seo et al. re-emphasized that caution should be exercised in adopting treatments based on non-randomized data [6]. It took more than a decade to collect sufficient cases of patients who received palivizumab for a multivariate analysis at one of the largest HCT centers. Palivizumab treatment appeared to be ineffective while being enormously expensive, with no apparent adverse outcomes. Thus, the generation of evidence that exceeds the “expert opinion” state must be accelerated. The relatively low incidence of some of these infections requires innovative surveillance and intervention networks among HCT centers worldwide. Future approaches to improving the speed and quality of treatment strategies could include multicenter, web-based studies of rare complications using detailed case report forms that allow outcome studies similar to those recently published for respiratory viruses and other pathogens [6,38,182]. Efforts have started to establish such networks and web-based disease surveillance and outcome databases have the potential to become an invaluable tool to generate evidence that is of higher reliability than expert opinion.

CHAPTER 92

HHV-6A, HHV-6B, HHV-7, and HHV-8 After Hematopoietic Cell Transplantation

Per Ljungman[1], Tetsushi Yoshikawa[2] and Katherine N. Ward[3]

[3] University College London, London, UK

Introduction

This chapter deals with the four most recently discovered herpesviruses: the human herpesviruses HHV-6A, HHV-6B, HHV-7, and HHV-8 (also called Kaposi sarcoma-associated herpesvirus). Early studies did not distinguish between the two viruses HHV-6A and HHV-6B but we today know that HHV-6B is the virus that causes the majority of the disease associated with HHV-6. The most important clinical manifestation of HHV-6B is encephalitis frequently localized to the limbic system. This complication is more common in severely T-cell-suppressed patients, for example after cord blood (CB) transplantation. Other clinical associations such as bone marrow suppression, pneumonia, and skin rash mimicking acute graft-versus-host disease (GVHD) have been proposed. The studies have been hampered, however, by the possibility of chromosomally integrated HHV-6 that is found in 1–2% of the population. Monitoring for HHV-6 has been proposed but is currently not generally recommended since there is no intervention of proven effectiveness. The importance of HHV-6A, HHV-7, and HHV-8 is less in stem-cell transplant recipients, although cases with likely pathology due to these viruses have been documented.

Human herpesviruses 6A and 6B

Epidemiology and basic virology

Human herpesvirus 6 (HHV-6) was discovered by accident in 1986 in CB lymphocyte cultures designed for the isolation of HIV [1]; the virus was initially named human B-lymphotropic virus but was later found to infect and replicate in lymphocytes of the T-cell lineage, at which point the name was changed to its present form. Soon after the discovery of HHV-6, it was realized that viral isolates fell into two readily distinguishable groups, HHV-6A and HHV-6B, and that they differ in their epidemiology and association with disease. The virus genomes are double-stranded DNA, 160–162kb in size and colinear with an overall nucleotide sequence identity of 90%, but interspecies divergence of specific sequences is higher than 30%. There is no genetic gradient between the two viruses and recombinants have not been reported [2]. In 2011, in the face of the accumulating evidence, the International Committee on Taxonomy of Viruses declared that HHV-6A and HHV-6B meet the formal definition of separate species. In what follows, the general term HHV-6 will therefore be reserved for instances where it is not necessary to distinguish HHV-6A from HHV-6B or where the distinction has not been made.

The two viruses are members of the herpesvirus subfamily *Betaherpesvirinae*, and of the *Roseolovirus* genus. As with the other herpesviruses, HHV-6A and HHV-6B persist for life following primary infection with the potential for transmission from human to human, for reactivation, particularly in the immunocompromised, and for consequent disease. HHV-6A and HHV-6B can infect a variety of cultured cell types but grow best in CD4$^+$ T-lymphocytes. Although these cells are the most frequently infected, the host range includes not only lymphoid cells and monocytes but also those of epithelial and neuronal origin. The explanation lies in the nature of the virus receptor – CD46 (also known as membrane cofactor protein, a regulator of the complement cascade) [3] – which is expressed on all nucleated cells.

The study of HHV-6 has been confounded by two issues that many investigations have not taken into account. The first is that despite the evidence, the need to distinguish HHV-6A from HHV-6B has not been generally appreciated. The second is that HHV-6 has a unique feature whereby either of the two viruses' genomic sequences can sometimes persist integrated into the human chromosome in a minority of persons (see the section Chromosomal Integration of HHV-6).

On the scanty evidence available, HHV-6A is commonly encountered in Central Africa [4], but rarely in the United States, the United Kingdom, and Japan. It is noteworthy that in contrast to its prevalence in the general population, HHV-6A is markedly overrepresented in cases of chromosomal integration. The true prevalence of HHV-6A infection due to horizontal transmission as opposed to chromosomal integration remains to be determined.

Primary infection with HHV-6B is universal, almost always occurring in early life with most children infected by the age of 2 years [5,6]. The virus is commonly found in saliva [7–9] and this is the probable source of transmission within families.

Since HHV-6B replicates in T-lymphocytes and is thought to be latent in monocytes and bone marrow progenitor cells [10,11], transmission via blood transfusion and organ transplant is to be expected. The first report of this was of primary HHV-6 infection in a patient following liver transplantation from a seropositive donor [12]. There have been isolated case reports since then,

including an infant who received a bone marrow transplant from his twin brother who had primary HHV-6B infection at the time of donation [13].

As regards disease, most children undergoing primary HHV-6B infection have at least some symptoms ranging from fever, sometimes accompanied by the rash of the childhood illness, exanthem subitum, to febrile convulsions, to status epilepticus with fever, and even to encephalitis [14–18]. After hematopoietic cell transplantation (HCT), HHV-6B reactivates and is the occasional cause of encephalitis and other manifestations (see below). No disease has been causally linked to HHV-6A although, intriguingly, there is a recent report of transmission of HHV-6A from a liver donor to recipient that was associated with syncytial giant cell hepatitis [19].

Chromosomal integration of HHV-6 (CIHHV-6)

This phenomenon, characterized by very high HHV-6 DNA loads in blood, is due to integration of full-length HHV-6A or HHV-6B DNA into host leukocyte chromosomes. Transmission of integrated viral DNA, occurring naturally in the germline, is unique amongst the human herpesviruses. CIHHV-6 was for many years considered an extremely rare occurrence, but it is now clear that it is uncommon rather than rare. Its frequency has been estimated as about 1% in UK blood donors [20] and in newborn children in the United States [21].

CIHHV-6 was first described in 1993 by Luppi et al. [22], who reported three individuals with viral DNA levels so high in leukocytes that they could be detected by Southern blotting and also by the very much more sensitive technique of polymerase chain reaction (PCR). Subsequently, fluorescence in situ hybridization (FISH) using HHV-6-specific probes identified integrated viral sequences in all three cases on chromosome 17 and close to, or in, the telomeres of the short arm [23]. Sequencing of the integration site has recently confirmed the telomeric location [24]. Since then, nine more sites have been found and always telomeric [25,26] (see the example in Figure 92.1), although on a seemingly random range of chromosomes and on either the short or long arms. The exact chromosome involved is unique to the individual.

Vertical transmission of CIHHV-6 was first reported in six different families in Japan [27–29] – in one family from both parents and in another through two generations. Since then, affected families have also been reported in Europe [30] and the United States [21], confirming that autosomal dominant inheritance of CIHHV-6 is a worldwide phenomenon. Since CIHHV-6 is in the germline, about one copy of HHV-6 DNA can be detected in every nucleated cell type in the body [31].

An important unresolved question is whether CIHHV-6 is associated with disease. This might occur in two ways, by virus reactivation or by disruption of telomere function. Considering the first possibility, of the very few studies conducted to date only one [32] has shown that integrated virus is capable of full replication in vivo. Regarding the second possibility, there are not nearly enough data available to unravel the possible long-term clinical consequences of HHV-6 integration at various telomeric chromosomal sites. In fact, no clinical consequences have been formally linked to CIHHV-6. Notably, CIHHV-6 has been found in a great many apparently healthy individuals, e.g. neonates [21], blood donors [20], and stem-cell donors [33].

In CIHHV-6, HHV-6 DNA can be found not only in whole blood but also in “cell-free” samples such as serum or plasma and cerebrospinal fluid (CSF), which contain human chromosomal DNA released from damaged cells during sample preparation. For most viruses, detection of significant levels of viral DNA in the blood, especially in serum or plasma, can be taken as evidence of active infection, but HHV-6 is an exception as such high viral DNA levels may be due to CIHHV-6. In the past, misunderstanding this has led to the inappropriate use of antiviral therapy [34]. Whereas multiple antiviral drug therapy has no effect on viral DNA levels in CIHHV-6 (Figure 92.2a), a good response was seen in a case of HHV-6-induced bone marrow suppression (Figure 92.2b). Diagnostic difficulties with CIHHV-6 also arise when the donor or recipient of HCT has CIHHV-6. If the donor has CIHHV-6, there will be elevation of HHV-6 DNA load in the recipient correlating with leukocyte engraftment and rising to characteristically and strikingly high levels [35]. On the other hand, if the stem-cell recipient rather than the donor has CIHHV-6, the converse will occur [36]. A comparison of the different possible findings regarding HHV-6 after HCT is given in Table 92.1.

Note that these signals overlap at the 22qtel region (arrowed). Source: Lohi O. et al. *Pediatr Blood Cancer* 2010; **55**: 1236–1238. Reproduced with permission of John Wiley & Sons.

Diagnosis of HHV-6 infection

Diagnosis of primary HHV-6 infection in young children is based on antibody detection using indirect immunofluorescence [37], but such tests are difficult to interpret in older children and adults. Immunofluorescence testing cannot distinguish between antibodies to HHV-6A and HHV-6B but a recently developed immunoblotting assay [38] has this capacity and may prove useful for research purposes. However, serology has no place in the routine diagnosis of HHV-6 infection in HCT recipients, and detection of virus or parts thereof is required.

One diagnostic possibility is the use of antigenemia tests [39], but there is limited experience as their use has not been widespread. The gold standard is virus isolation in CB lymphocytes, but this is a

specialized technique that is slow, labor-intensive, and not available to most diagnostic laboratories. The need is for rapid diagnosis and the norm is to use PCR to detect viral DNA in blood. The type of sample investigated varies between laboratories but the most commonly used are whole blood and plasma. In view of the differing natural histories of HHV-6A and HHV-6B (see above), it is advisable to use a quantitative PCR that distinguishes between the two [40], but this has rarely been attempted because the need to distinguish the two viral species was not recognized.

If CIHHV-6 is suspected, it can most easily be established by checking donor and recipient samples obtained prior to transplant for the characteristic high levels of HHV-6 DNA in blood using quantitative PCR. Viral DNA load in whole blood or leukocytes should be compared with the amount of cellular DNA, for example that of β-globin, so as to confirm that there is at least one copy of HHV-6 DNA per cell [41,42]. Further confirmation can be gained by testing hair follicles or nails [29,43].

Clinical manifestations in HCT patients

As already described, HHV-6 is now divided into two different viruses, HHV-6A and HHV-6B, and molecular epidemiological studies have demonstrated that HHV-6B, rather than HHV-6A, reactivation frequently occurs in HCT recipients [44]. Although

Table 92.2 Other symptoms and diseases that have been suggested to be associated with HHV-6 infection

Interstitial pneumonitis
Bone marrow suppression
Graft-versus-host disease
Skin rash
Induction of CMV reactivation
Indirect immunosuppression

several symptoms and diseases have been suggested to be associated with HHV-6 infection in HCT recipients, proof remains elusive except for the case of post-transplant HHV-6 encephalitis (see below). As HHV-6 is similar to cytomegalovirus (CMV), another betaherpesvirus, which causes disease in HCT recipients, similar symptoms or diseases have been anticipated as a result of HHV-6 infection (Table 92.2). Interstitial pneumonitis has been postulated to be associated with HHV-6 infection [45,46] because quantitative PCR analysis demonstrated large quantities of HHV-6 DNA in lung tissue obtained from such patients [45,46]. Additionally, HHV-6 antigens were also detected in the lung tissue obtained from interstitial pneumonitis patients, suggesting viral replication [45]. However, many other pathogens including CMV have to be eliminated to authenticate a positive correlation between HHV-6 and this disease. Bone marrow suppression is another possible important syndrome in which HHV-6 might be involved [47,48] since delayed platelet or monocyte engraftment has been found in HCT recipients with HHV-6 infection in several in vivo studies [49–54]. Furthermore, direct and indirect suppression of bone marrow progenitor cell proliferation have been demonstrated in vitro [55–57].

It is well known that HHV-6 reactivation generally occurs between 2 and 4 weeks after transplant, which coincides with the usual time period of acute GVHD. Hence an association between HHV-6 infection and acute GVHD, or skin rash resembling acute GVHD, has been suggested on the basis of numerous cohort studies [52,58–61]. Several investigators detected viral DNA in skin obtained from patients with acute GVHD [62,63]. Additionally, it was demonstrated that HHV-6 can upregulate surface molecules such as ICAM-1 on epidermal cells [64], which are considered to be important molecules for pathogenesis of acute GVHD. However, the major problem of determining the precise role of HHV-6 in the pathogenesis of acute GVHD has yet to be resolved. There are two possible relationships between HHV-6 and acute GVHD: HHV-6 could be a trigger for acute GVHD, because this virus can modulate the host immune responses, but on the other hand, acute GVHD could induce HHV-6 reactivation in HCT recipients. Hence future in-depth analysis is needed to elucidate an association between acute GVHD and HHV-6 infection. It has been shown that HHV-6 reactivation after HCT is associated with increased non-relapse mortality [52,65], and similar findings have also been reported in solid organ transplant recipients [66]. Secondary immune suppression induced by HHV-6 reactivation might be involved in this increase in patient mortality; however, it is difficult to determine a truly causal relationship between HHV-6 reactivation and the mortality rate in transplant recipients. In the absence of an intervention of proven effectiveness (see below), the best management of asymptomatic patients with HHV-6 DNAemia is currently unknown.

HHV-6 encephalitis

The most important and severe consequences of HHV-6 reactivation among post-transplant patients are caused by involvement of the central nervous system (CNS). HHV-6 can cause viral encephalitis but is also associated with other less overt neurologic symptoms [52,67]. In a large prospective study, Zerr et al. showed that HHV-6 detection in plasma was significantly associated with delirium and neurocognitive decline during the first months after HCT [68]. The long-term impact of these findings is still to be investigated and also whether any prophylactic intervention can reduce the risk.

In a recently published study, HHV-6 was the most common cause of viral encephalitis, being found in 28% of cases after allogeneic HCT [69]. It is of note that a number of patients in this series of cases with viral encephalitis had HHV-6 detected together with other viruses. In addition, several case reports and small case series have been published, although some of the early ones are most likely to have been hampered by not excluding CIHHV-6 [67,70–80]. The majority of HHV-6 encephalitis cases occur during the first month after HCT, matching the pattern of the HHV-6 peak viral load in plasma, which is also an early event [52,59,81].

Symptoms

The clinical picture of post-transplant acute limbic encephalitis (PALE) has been described as a typical feature of HHV-6 encephalitis. This fits with that the tropism of HHV-6 for astrocytes in the hippocampus [74,82]. Common symptoms are short-term memory loss, confusion, disorientation, and depressed consciousness [79,83]. Seizures are also fairly frequent whereas focal neurological deficits have been reported but seem to be uncommon. Another reported complication of HHV-6 CNS infection is the syndrome of inappropriate antidiuretic hormone secretion (SIADH) [83,84]. However, HHV-6 encephalitis can also affect other areas of the brain, although less frequently.

Risk factors

Although HHV-6 is a virus usually recognized as a pathogen in children, most published cases of HHV-6 encephalitis have occurred in adults. The large majority of such cases have been reported in allogeneic HCT recipients and only a few after autologous HCT. Acute GVHD grade II–IV is commonly reported in the different case series as are the use of human leukocyte antigen (HLA)-mismatched or unrelated donors [81,85]. Vu et al. reported an 11.6% incidence of HHV-6 encephalitis in patients receiving an alemtuzumab-containing regimen [86]. Patients undergoing HCT from CB donors seem to be at an increased risk for HHV-6 encephalitis [85,87]. Recently, a systematic review was performed which showed a risk of 8.3% in CB graft recipients compared with 0.5% in recipients of other graft sources [88]. It also showed that HHV-6 detection in plasma was twice as common in CB graft recipients (72% vs. 37%). Hill et al. recently reported a large retrospective cohort of 1344 patients and found that risk factors for HHV-6 PALE were unrelated CB HCT [adjusted hazard ratio (aHR) 20.0, $p < 0.001$], acute GVHD grades II–IV (aHR 7.5, $p < 0.001$), and adult mismatched donors (aHR 4.3, $p < 0.04$) [85]. All these risk factors support the importance of poor T-cell function as a component in the pathogenesis of HHV-6 encephalitis. It has also been reported that plasma interleukin (IL)-6 levels are increased before the development of HHV-6 encephalitis together with high HHV-6 viral load in plasma, suggesting that systemic inflammation is involved in the pathogenesis [89].

Findings

HHV-6 encephalitis is typically defined as the presence of CNS dysfunction, a positive PCR result for HHV-6 DNA in the CSF, and the absence of other identified causes of CNS dysfunction [80,90].

Other definitions have been used, such as high levels of HHV-6 DNA in blood instead of in CSF, or adding the requirement of limbic involvement shown by magnetic resonance imaging (MRI) of the temporal lobe. It has also been suggested that the likelihood is increased when the viral load is high in plasma [91]. Hill et al. produced receiver-operating characteristic (ROC) curves analyzing the sensitivity and specificity of plasma viral load and found that a level of $\geq 10^5$ copies/mL was 80% sensitive and 86% specific for HHV-6 PALE [85]. If the level was increased to $\geq 10^6$ copies/mL, the sensitivity decreased to 30% and the specificity increased to 97%. However, they did not exclude the possibility of CIHHV-6. These definitions without CSF verification can be used as a pragmatic definition if a lumbar puncture cannot be performed, but then CIHHV-6 must be excluded. Although detection of viral DNA in CSF supports the diagnosis of HHV-6 CNS involvement, it is not absolutely diagnostic. Wang et al. showed that HHV-6 DNA can be detected in CSF in a small proportion of non-symptomatic immunocompromised individuals [80], and this might well be due to chromosomal integration [92]. HHV-6B is the most commonly reported type, although HHV-6A detection has also been described [71,93]. There are no typical non-specific findings in CSF; many patients have a slight pleocytosis with mononuclear cell predominance but cell counts can also be normal. CSF protein levels can be increased.

At autopsy of patients dying from HHV-6 encephalitis, findings seen in affected areas of the brain were characterized by loss of neurons, reactive gliosis, demyelination, and lymphocyte infiltration [74,93,94].

A “typical” MRI finding has been described showing symmetric or non-symmetric inflammation within the medial temporal lobe, including the uncus, amygdala, entorhinal area, and hippocampus – “limbic encephalitis” – although other imaging patterns such as leptomeningitis are also seen (Figure 92.3) [83,95–97]. These changes of limbic encephalitis and edema can be found early after the onset of clinical signs of encephalitis. However, these are not pathognomonic for HHV-6 encephalitis since other organisms including HSV and VZV can give similar appearances on MRI [98]. A computed tomography (CT) scan is usually normal during the acute phase but can show hypodense lesions in the temporal lobe during follow-up. Electroencephalogram (EEG) abnormalities are also common in HHV-6 encephalitis.

Provenzale et al. compared clinical and MRI findings in nine patients positive for HHV-6 DNA in CSF and seven patients who were tested but found negative for HHV-6 DNA [99] and reported that hippocampal changes were similar in both HHV-6 CSF-positive and -negative patients whereas extrahippocampal involvement or abnormalities in the entorhinal cortex or amygdala were more common in HHV-6-positive patients [99].

Outcome

HHV-6 encephalitis has been reported to be associated with a high rate of mortality and also significant late sequelae. Zerr reviewed the literature in 2006 and found among 44 cases an HHV-6-associated mortality of 25% whereas 14% died of other causes after showing some improvement [93]. Of the survivors, 43% made a complete recovery and 18% had long-term neurological deficits. In more recent series, Seeley et al. found that five out of nine (56%) adults with HHV-6-positive PALE died, and three out of four (75%) of the surviving patients maintained persistent cognitive impairment [83]. Hill et al. reported that death due to HHV-6 PALE occurred in 50% of CB recipients (5/10) compared with none (0/9) who received adult donor stem cells [85]. These two papers come from the same institution and the case collections overlap in time, so some cases presumably are the same. Muta et al. described 23 patients from Japan of whom two died, 11 (48%) recovered, and 10 (44%) had long-term memory loss [81]. In another survey of eight Japanese patients with HHV-6 encephalitis, three died and four of the five patients who survived suffered from permanent neurologic disability [87]. Vu et al. reported that four out of five adults developing HHV-6 encephalitis survived without neurologic consequences [86]. In a follow-up of four previously published cases from Karolinska University Hospital [80], all recovered without sequelae (P. Ljungman, unpublished results). Howell et al. reported the development of generalized epilepsy in three children 11–18 months after PALE, together with cognitive abnormalities and delayed intellectual development [100].

Management of HHV-6 infections

In vitro studies suggest that HHV-6 is susceptible to foscarnet, ganciclovir, and cidofovir, and moderately susceptible to acyclovir. No controlled study has been performed, however, with any antiviral drug. Zerr et al. reported decreases of HHV-6 viral loads in CSF or serum during ganciclovir or foscarnet therapy [101]. Ljungman et al. reported reductions in saliva viral load in asymptomatic patients receiving ganciclovir for preemptive therapy of CMV [102]. Hill et al. treated 18 patients with HHV-6 PALE with foscarnet 180mg/kg/day and reported improvements in the symptoms of most patients [85]. Schmidt-Hieber et al. reported a response rate of 63% with either foscarnet or ganciclovir therapy of HHV-6 encephalitis [69]. Vu et al. reported responses in four out of five patients treated with foscarnet [86]. Since the outcome of HHV-6 encephalits is poor, preemptive therapy with foscarnet or ganciclovir was investigated in two uncontrolled studies of patients with high HHV-6 viral loads in plasma [91,103] and in both there were cases of encephalitis that developed concomitantly with the detection of HHV-6 in plasma, suggesting only limited effectiveness of a preemptive strategy. There are no good published data regarding the treatment of other possible clinical manifestations of HHV-6.

Ideally, the primary step in high-risk patients should be to prevent HHV-6 reactivation. Unfortunately, there is no effective drug available that can be given prophylactically since valganciclovir is too toxic in the highest risk groups such as CB recipients and long-term foscarnet prophylaxis is impractical since it can only be given intravenously. Breakthrough cases have also been reported during prophylaxis with foscarnet [104], valaciclovir or acyclovir, and valganciclovir [86]. An interesting drug in development is CMX001, a lipid conjugate of cidofovir, that can be given orally and that has efficacy in vitro against HHV-6 and also against several other viruses of importance in high-risk HCT recipients [105]. Since HHV-6-associated complications occur in the presence of suppressed T-cell function, adoptive transfer of T cells could be a preventive or therapeutic strategy. Recently, it was reported that it is possible in vitro to generate T cells with multivirus specificity including HHV-6 activity [106]. However, there is so far no report regarding the clinical use of such cells and the effect on HHV-6-associated complications.

Human herpesvirus-7

Epidemiology and basic virology

HHV-7 is a T-lymphotropic virus belonging to the *Roseolovirus* genus of the betaherpesviruses together with the closely related viruses HHV-6A and HHV-6B. The HHV-7 genome is 153kb in size and over 90% of its genes are similar in amino acid sequence to those of HHV-6. There are only a small number of genes in HHV-7 where there is not a counterpart in HHV-6 and vice versa.

Similarities to HHV-6B include the following: HHV-7 is commonly found in saliva, which is the probable source of transmission within families [107,108]; infection is almost universal and occurs early in childhood, being gradually acquired over the first 5–6 years of life [109]; primary HHV-7 infection has been much less extensively investigated than HHV-6 infection but the pattern of disease is similar [15,110–113].

Features of HHV-7 that differ from HHV-6 include the following: the viral cellular receptor for the infection of T-lymphocytes is CD4, rather than CD46 [114]; tropism is restricted compared with HHV-6; HHV-7 has rarely been found in brain tissue but is found not only in blood and saliva but also in lungs, skin, and mammary glands [115] as the virus can infect cells that do not express detectable CD4; $CD4^+$ T cells have been proposed as a site of latency [116]; and HHV-7 is not vertically transmitted [117] and there is no evidence of viral chromosomal integration.

The general comments above on the diagnosis of HHV-6 infection apply equally to HHV-7, but in the latter case much less developmental work has been carried out on molecular and antibody tests [36,118].

Clinical manifestations in HCT patients

The impact of HHV-7 after HCT has been examined in longitudinal studies [119–121]. In contrast to HHV-6B, HHV-7 reactivation after HCT is relatively infrequent [122]. So far, it has not been possible to assign a clinical syndrome to HHV-7, with the exception of single case reports describing CNS infection with optic neuritis, encephalitis, or myelitis in stem-cell transplant recipients [122–125].

Human herpesvirus-8

Epidemiology and basic virology

HHV-8 (also known as Kaposi sarcoma-associated herpesvirus) is a gammaherpesvirus similar to Epstein–Barr virus (EBV). It is the cause of Kaposi sarcoma but has also been associated with primary effusion lymphoma and multicentric Castleman disease. The prevalence of HHV-8 infection is very high (>50%) in older children and adults in Africa and parts of the Amazon basin, intermediate (5–20%) in the Mediterranean, Middle Eastern countries, and the Caribbean, and low (<5%) in North America, northern Europe and Asia (<5%). The prevalence of infection is also very high in homosexual men in whom the virus is transmitted sexually. The virus is also transmitted non-sexually, probably via saliva, in areas of high endemicity. HHV-8 is latent in B-lymphocytes and may be transmitted by blood transfusion [126]. As regards diagnosis of HHV-8 infection, the general comments above on the diagnosis of HHV-6 and HHV-7 infection apply equally to HHV-8. Methods exist to detect HHV-8 DNA by quantitative PCR using whole blood, plasma or serum.

Clinical manifestations in HCT patients

Case reports suggest that HHV-8 can cause febrile syndrome and marrow failure in HCT recipients [127,128]. Although transmission from donor to recipient has been documented in the kidney transplant setting, there have been no reports of transmission via stem cells or CB to date [129]. In contrast to HIV-infected patients in whom HHV-8-associated Kaposi sarcoma develops after many years of severe T-cell dysfunction, only a few cases of have been reported in HCT recipients [130–132]. The reason why HHV-8 is not a significant pathogen in HCT recipients may be because very few patients until now coming to transplant are seropositive, and in those who are seropositive T-cell function is reconstituted too fast for the sarcoma to develop.

Conclusion and future development

HHV-6B is an important pathogen in HCT patients primarily through its CNS effects. The risk is highest in patients after CB transplantation and this is a group where it would be logical to implement preventive measures. However, there is no clearly documented effective strategy, for several reasons. We need in the future to differentiate clearly active viral replication from CIHHV-6. We also will need good controlled studies of either a prophylactic or preemptive strategy. There is currently no ideal antiviral available for testing such a strategy, although foscarnet has been best studied. CMX001 is a drug in clinical development that might be a future alternative. Adoptive transfer of HHV-6-specific T cells might also be a possible management strategy. We need more knowledge regarding the importance of HHV-6A as a pathogen in HCT recipients. HHV-7 and HHV-8 are rarely significant pathogens after HCT.

CHAPTER 93

Human Adenovirus, Polyomavirus, and Parvovirus Infections in Patients Undergoing Hematopoietic Stem Cell Transplantation

Hans H. Hirsch[1] **and Steven A. Pergam**[2]

[1]University of Basel and University Hospital Basel, Basel, Switzerland
[2]Fred Hutchinson Cancer Research Center and University of Washington School of Medicine, Seattle, WA, USA

Introduction

The human adenovirus (HAdV), polyomavirus (HPyV), and parvovirus B19 (HPVB19] are small non-enveloped DNA viruses that differ in virion organization, epidemiology, and primary diseases in the human population. In hematopoietic cell transplantation (HCT) patients, however, HAdV, HPyV, and HPVB19 may cause some overlapping syndromes such as pneumonia, hemorrhagic cystitis, hepatitis, and central nervous system (CNS) disease. Specific laboratory tests such as the nucleic acid amplification testing (NAT) are most frequently used to differentiate one from another and from other etiologies. The propensity of these viruses to persist in an infected host or to establish latent infections limits the interpretation of NAT results when trying to distinguish a relevant cause of infectious disease from mere persistence or low-level reactivation. This can be partly addressed by applying increasingly accepted definitions distinguishing infection, replication and disease (Table 93.1). Moreover, these non-enveloped viral agents share a relative resistance to inactivation that has potential implications for healthcare-associated transmission through contaminated surfaces, instruments, and blood products. Only HAdV encodes a viral polymerase that could specifically be targeted by antivirals such as cidofovir, whereas the smaller HPyV and HPVB19 are dependent on host cell polymerase activity for efficient viral replication. Release of progeny virions is thought to occur in bursts of lysing host cells, thereby restricting the main protective effects of antibodies to neutralization and opsonization of extracellular virions and leaving little role for antibody-mediated cytotoxicity. Therefore, control of viral replication largely depends on recovering immune responses, and on virus-specific T-lymphocytes in particular.

Human adenovirus

Human adenovirus (HAdV) species can infect a variety of mucosal sites and cause conjunctivitis, upper respiratory tract infectious disease (RTID), gastroenteritis, and cystitis in immunocompetent individuals; organ-invasive and disseminated HAdV are rare in immunocompetent hosts. By contrast, HAdV replication is associated with life-threatening events in very young, presumably immunologically naïve children and in immunocompromised individuals [1,2]. HCT recipients, in particular children, are at increased risk for severe HAdV manifestations, including lower RTID, hemorrhagic cystitis (HC), nephritis, invasive gastroenteritis, and disseminated HAdV disease. Unfortunately, there are few treatment options, and mortality associated with HAdV disease is very high unless immunologic recovery, particularly of T-lymphocyte function, is observed.

Epidemiology

HAdV transmission occurs primarily through respiratory pathways in airborne droplets and through person-to-person contact. HAdV can also be transmitted through water sources, fomites, and even medical equipment, leading to outbreaks of disease [3]. HAdV shedding can occur persistently and intermittently for several months or years in healthy children, making acquisition by horizontal transmission a major mode of exposure [4].

Immunodeficient patients are at increased risk for complications from primary infection and also from reinfection from exogenous, or possibly endogenous, sources, although the sites and mechanisms of HAdV persistence/latency are not well characterized. It is thought that replication of a persistent strain is the principal mechanism for disease in the adult HCT population, whereas primary infection or reinfection with new HAdV strains to which the host has no prior immunity plays a key role in pediatric HCT recipients [5,6]. Accordingly, pediatric HCT recipients are more likely to develop HAdV DNAemia (20–26% vs. 5–9%) and invasive HAdV disease after transplantation [7]. The risk factors for HAdV DNAemia and associated organ-based disease are T-cell-depleted transplantation, cord blood grafts, graft-versus-host disease (GVHD), immunosuppressive therapy, and lymphopenia (<200–300μL) [8–11]. In HCT patients, the majority of HAdV events occur during the first 100 days after transplantation.

Virologic aspects

HAdV are large (90–100nm), non-enveloped icosohedral, double-stranded DNA viruses of the family Adenoviridae [1]. HAdV are highly infectious and their non-enveloped virologic structure allows them to remain stable in most environments [3]. They are categorized in seven subgroups A–G, and there are over 50 serotypes (Figure 93.1) [12]. After exposure of mucosal surfaces, HAdV infects epithelial cells and can then be detected in lymphoid

tissues, such as the tonsils, adenoids, and/or the gastrointestinal (GI) tract [13]. The most common site of entry during primary infection uses the cocksackie and adenovirus receptor (CAR), except in HAdV subgroup B, which are thought to use CD46 [14]. The HAdV DNA polymerase is critical to intracellular replication, and can be inhibited by cidofovir. Viral proteins encoded by the viral E3 transcription unit likely help the virus avoid host immunologic responses [15]. The exact mechanism and clinical relevance of persistence versus latency are a subject of current research [15].

HAdV elicits both humoral and cellular immune responses. Neutralizing antibodies targeting hexon, penton base, and fiber proteins of the outer virus capsid convey some degree of protection against specific HAdV serotypes [16]. Since CD4$^+$ and CD8$^+$ T-cell responses are important to viral clearance after transplantation, delayed recovery and function of lymphocytes after HCT are associated with the development of prolonged HAdV replication and disease [11,17].

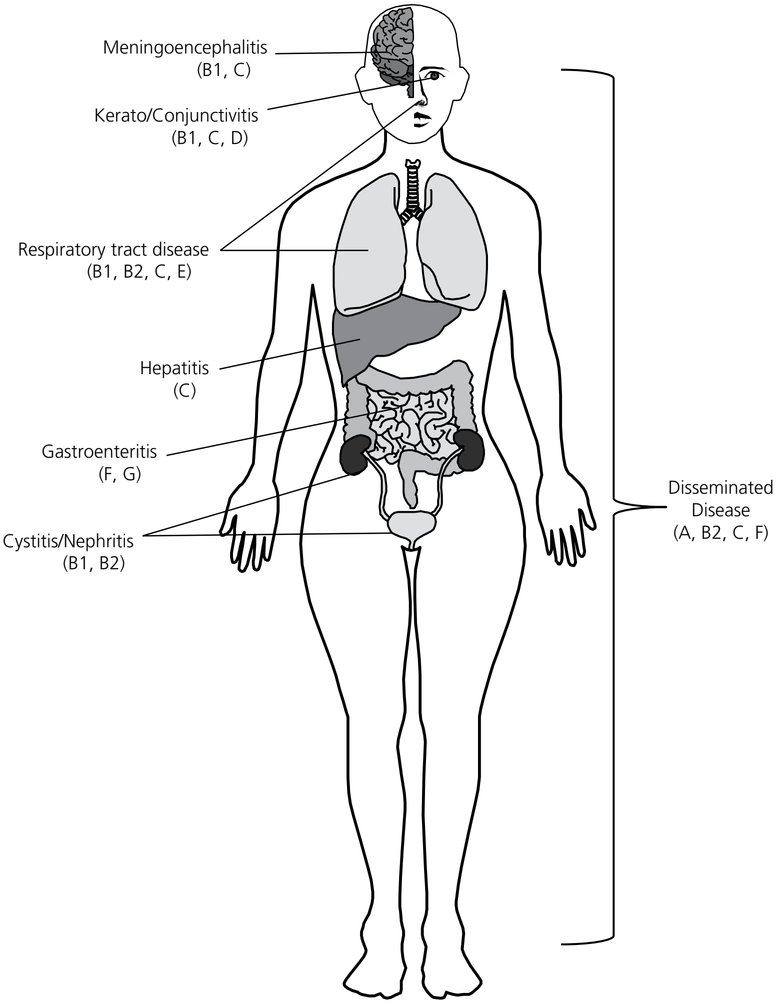
Table 93.1 Working definitions of infection, replication, and disease caused by human adenovirus, polyomavirus, and parvovirus in HCT patients

Virus infection – Evidence of virus exposure by detecting specific immune responses (epitope-specific antibody or T-cells) or by detecting viral antigens, nucleic acids
Asymptomatic virus replication – Evidence of viral replication by increasing viral loads, virus isolation by culture, or direct antigen detection in patient specimens without clinical symptoms or signs of organ disease
Probable virus disease – Evidence of viral replication plus compatible symptoms and signs of viral syndrome or organ disease, but without histological confirmation available and another etiology
Proven virus disease – Evidence virus replication plus corresponding specific histopathology

Diagnostic methods

There is currently no role for the determination of HAdV antibodies in HCT donors, recipient screening, post-transplant diagnosis, or follow-up, owing to the widespread exposure and serologic cross-reactivity of available assays, and the unreliable antibody responses in patients undergoing HCT. Similarly, the assessment of HAdV-specific cellular immune responses is not routine in clinical care, although increasing responses in peripheral blood mononuclear cell (PBMC) preparations have been associated with protection. Therefore, key diagnostic procedures focus on the demonstration of HAdV replication. Virus isolation by culture by conventional systems has a turnaround time of approximately 1–3 weeks, limiting its clinical use [1]. Culture by shell vial methods improves the sensitivity of detection and reduces the turnaround time to 2–3 days [18]. Direct antigen detection for HAdV is based on either particle agglutination assays, fluorescence-labeled monoclonal antibodies, or enzyme immunoassays combined with capillary chromatography. Direct antigen detection is typically

Subgroups	Serotypes
A	12, 18, 31
B1	3, 7, 16, 21, 50
B2	11, 14, 34, 35
C	1, 2, 5, 6
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51, 53, 54
E	4
F	40, 41
G	52



Meningoencephalitis (B1, C)
Kerato/Conjunctivitis (B1, C, D)
Respiratory tract disease (B1, B2, C, E)
Hepatitis (C)
Gastroenteritis (F, G)
Cystitis/Nephritis (B1, B2)
Disseminated Disease (A, B2, C, F)

applied to stool suspensions using agglutination assays, and less frequently to nasopharyngeal aspirates, nasopharyngeal swabs suspended in virus transport medium, bronchoalveolar lavage, tracheal aspirates typically using other tests such as capillary immunoassays. Direct antigen detection usually requires only 15–30 minutes, thereby reducing the turnaround time to less than 2 hours, but is less sensitive than NAT, e.g. such as polymerase chain reaction (PCR) [18]. Therefore, direct antigen detection is often used as initial point-of-care testing of specimens in pediatric and severely immunocompromised patients who are more apt to have high viral loads.

In most centers, NAT has become the main method for HAdV detection in HCT patients as it can be performed on all routine specimens (blood, respiratory secretions, urine, stool, CSF) and also tissue samples [19,20,21]. NAT provides both high sensitivity and specificity, and can be performed in multiplex assays and (semi-) quantitation, which has been explored for predicting outcome and monitoring treatment. The detection of HAdV in the blood is usually a marker of severe disease and risk of dissemination, although asymptomatic low-level HAdV viremia has been described, particularly in children [22]. Detection of HAdV DNAemia occurs in approximately 6–28% of pediatric and 0–6% of adult patients undergoing HCT [23]; some centers report rates that are much higher, particularly in pediatric patients [24]. High serum HAdV viral loads of >10,000 copies/mL in most studies [25,26] have been linked to organ disease, dissemination, and subsequent mortality. NAT can also be used to detect specific HAdV genotypes, which can be helpful in evaluating nosocomial transmission or point source outbreaks [27]. Typing of HAdV has indicated that several different strains can replicate sequentially or simultaneously after HCT [27,28]

Clinical manifestations

Serotypes from all seven subgroups can cause disease in both immunocompetent and immunocompromised subjects (Figure 95.1) [1]. Definitions of HAdV replication and disease have varied in prior publications, but the recently updated European guidelines propose the combination of clinical data, virology results, and histopathology [20], similar to the definitions proposed for BKPyV [29] JCPyV [30] and other HPyVs in transplantation [31] (Table 95.1).

Respiratory HAdV disease

In the first 100 days after transplantation, HAdV makes up approximately 5–6% of all respiratory viral infections in HCT patients [32]. Typical symptoms are sore throat, fever, and cough, but not all patients with HAdV upper respiratory infections have symptoms [22]. Upwards of 25% will progress to lower tract disease (Figure 93.2) [33,34], followed by respiratory failure and ultimately death in 40–70% of patients (7,32). The most severe cases are characterized by HAdV DNAemia and dissemination.

Gastrointestinal HAdV disease

HAdV types can lead to acute gastroenteritis during primary infection, and can reemerge after HCT following re-exposure or from GI sites of persistence [13]. Patients with GI disease typically present with diarrhea, which is difficult to distinguish from other, occasionally simultaneously occurring, infectious and non-infectious causes, most notably GVHD; more severe GI manifestations such as hemorrhagic colitis can also occur [35]. Because patients can shed HAdV asymptomatically in stools, mere qualitative detection of HAdV may not be indicative of disease. However, HAdV loads in stools increasing to very high levels of >6 $\log_{10}$ copies/mL has been used for screening and identifying pediatric HCT patients at risk for HAdV viremia and disseminated disease [36].

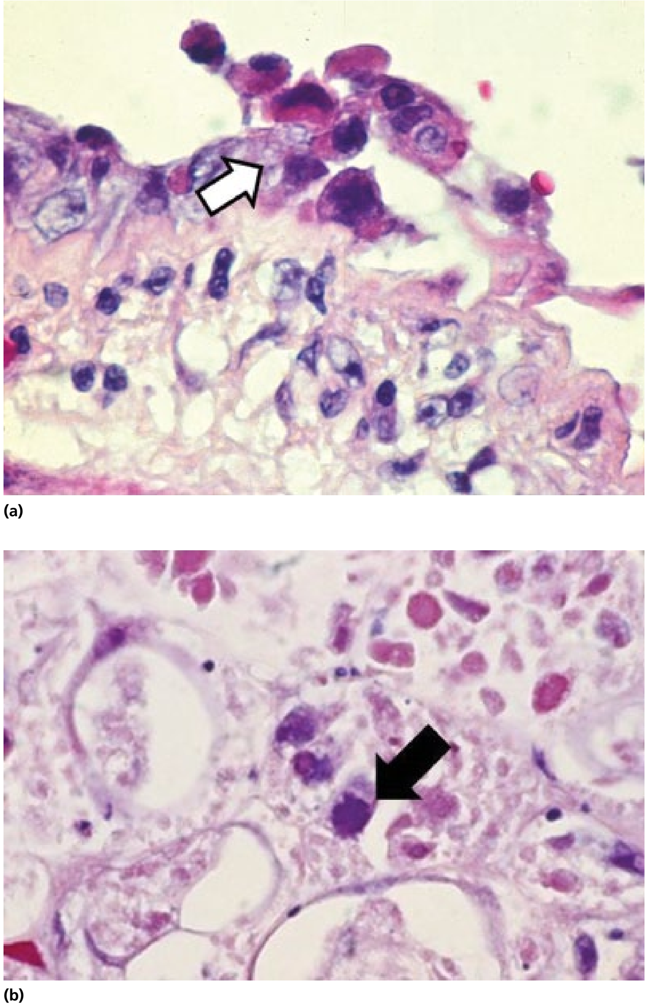

Figure 93.2 Adenovirus findings on histopathology. (a) Hematoxylin and eosin (H&E)-stained tracheal epithelial cells. This image demonstrates a cluster of dark-staining cells infected by adenovirus (white arrow). There is a progression of nuclear changes as the virus replicates and finally a dark-staining "smudge cell" is formed. (b) H&E-stained mucosal biopsy, demonstrating a smudge cell (black arrow) where basophilic inclusions have encompassed the entire nucleus. Source: reproduced with permission of Robert Hackman MD.

Hepatobiliary HAdV disease

Liver involvement after transplantation is less commonly diagnosed than GI HAdV disease. Liver enzyme elevations have been reported and are at times difficult to distinguish from other etiologies, including drug toxicity and GVHD. Fulminant hepatic failure from HAdV either in combination with viral dissemination or as the primary manifestation of the disease has been described in HCT patients [37,38]. In these cases, liver biopsies or post-mortem tissues demonstrate hepatic necrosis, cholestasis, and hepatocytes with intranuclear basophilic inclusions ("smudge cells") (Figure 93.2) [38]. Outcomes in patients with severe liver disease are very poor, despite aggressive treatment attempts [37–39].

Renourinary HAdV disease

HAdV shedding in the urine has been reported in 1–5% of HCT patients. HAdV is more readily associated with urologic symptoms and signs than JCPyV and BKPyV, suggesting a higher intrinsic pathogenic potential (Table 93.2). Most HCT patients present with self-limited dysuria and mild HC [40]. HAdV-associated HC is

Table 93.2 Diagnosis of virus-associated hemorrhagic cystitis

1. Clinical signs of cystitis	
Dysuria, urge, frequency, lower abdominal discomfort	
2. Hematuria grade II and higher	
Grade I	Microscopic hematuria (>100 erythrocytes per high-power field)
Grade II	Macrohematuria
Grade III	Macrohematuria with clots
Grade IV	Macrohematuria with urinary obstruction and postrenal failure
3. Viral replication in urine	
For BKPyV	Urine viral load >$7\log_{10}$geq/mL; plasma viral loads increasing above $4\log_{10}$geq/mL
For HAdV	Urine viral loads not defined (>$5\log_{10}$geq/mL?)
Plasma viral loads not defined (>$3\log_{10}$geq/mL?)	
4. Exclude major contribution of other etiology	
Infectious	Bacteria, other virus including cytomegalovirus, fungus, parasite
Urotoxic	Early onset <2 weeks of conditioning, cyclophosphamide, busulfan, total body irradiation, insufficient uroprotection with forced diuresis and mesna
Hematologic	Bleeding disorder, low platelets, graft-versus-host disease
Malignant	Urothelial carcinoma, other primary or metastasizing neoplasia
Mechanical	Catheter, ureteric stenosis, stenting or other procedure

characterized by macroscopic hematuria grade II–IV, clinical signs of cystitis with urgency, frequency, abdominal discomfort, immobilizing pain, and/or urinary obstruction. Progression to HAdV-associated tubulointerstitial nephritis and disseminated HAdV disease can occur [41], and HAdV-associated nephritis is primarily seen in conjunction with HC. HAdV nephritis often leads to progressive renal failure and is a strong predictor of HAdV-associated death [3,42]. Although less frequent than BKPyV-associated HC and nephropathy, HAdV is more likely to cause renourinary disease in patients with more profound immunosuppression, particularly those who have undergone T-cell-depleted transplants [43]; rates are much lower in autologous transplant recipients [44].

Neurologic HAdV disease

Neurologic complications, particularly encephalitis, are extremely rare HAdV complications in HCT [45,46]; pediatric patients make up the majority of cases. A large study of 11 German transplant centers detected HAdV in 3% of all encephalitis cases [47]. The affected patients can present with fever, headache, seizures, or mental status changes. Interestingly, not all patients who present with CNS disease have evidence of DNAemia and dissemination [46].

Disseminated HAdV disease

Systemic/disseminated HAdV replication is defined by detection of HAdV replication in ≥2 end organ sites or detection of HAdV in peripheral blood. Severe local disease may progress to disseminated disease [2,11]. Pediatric patients are at the highest risk for dissemination, and those who undergo cord blood transplantation or need immunosuppression for high-grade GVHD appear to dominate adult cases [8,9]. Mortality associated with dissemination is high at 60–80% [7,39].

Treatment

Patients with probable, proven, and disseminated HAdV disease in HCT should be considered for treatment. In line with the key risk factors of HAdV disease, improving HAdV-specific immune function is considered a cornerstone of treatment. Ideally, this involves improvement of immunologic function, but is often difficult or impossible with concurrently active GVHD. Moreover, recovery of HAdV-specific immunity may be impaired or prolonged as a result of the underlying disease, the conditioning regimen intensity, GVHD prophylaxis, corticosteroids, the administration of long-lasting lymphocyte-depleting agents such as alemtuzumab, or the use of a cord blood graft. Therefore, antiviral drugs has been widely used despite considerable limitations in efficacy and appropriate clinical studies.

Antiviral drugs

There are no approved antiviral drugs for the treatment of HAdV replication and disease. Ribavirin and cidofovir have been most frequently utilized for treatment, although neither of these agents has been evaluated in a randomized clinical trial for HAdV treatment. Cidofovir may be a more effective first-line therapy [4,9,48,49], but primarily renal, less so bone marrow toxicity, limit its routine use (Table 93.3). For ribavirin, some studies have reported no benefit [37], whereas others claim significant clinical improvements [50]. Data reported by Morfin et al. suggest that the susceptibilities of HAdV may differ for different subtypes, as ribavirin was only effective against non-C adenovirus infections, whereas cidofovir was effective in vitro against all subtypes [51]. A novel lipid conjugate of cidofovir brincidofovir (CMX001) is currently in randomized clinical trials, and early reports are encouraging [42], particularly since the drug has a less toxic profile than its parent drug. Ganciclovir and other nucleoside analogs have also been reported to have potential activity against HAdV (e.g. due to high concentrations in urine), but are not used as either first- or second-line therapy at most centers [5]. Current data purporting the major benefits of antiviral therapy must be interpreted with caution. Outcome data are confounded in the context of immune reconstitution, particularly since survival is affected by the kinetics of lymphoctye recovery [17,52].

Immunotherapy

In general, intravenous immunoglobulin (IVIg) can be considered as adjunctive therapy in patients with HAdV infections; however, the large number of serotypes may limit any major benefits. The use of adoptive immunotherapy is currently undergoing active trials, and initial data using expanded HAdV/viral-specific T cells have demonstrated excellent response rates [53,54]. Recent data from Leen et al. demonstrated that 14/18 (78%) of patients with severe HAdV disease had a complete or partial response to banked multiviral-specific T cells, showing the feasibility of such approaches [55]. However, costs and time requirements have limited their utility to only a few specialized centers. As newer rapid selection methods and "off-the-shelf" products are developed, these approaches may become more readily available for patients with severe disease [55,56].

Prevention

Screening and preemptive treatment

The limited available data suggest that weekly NAT screening and preemptive cidofovir therapy may reduce the development of HAdV disease in high-risk patients [49,57]. Some centers currently utilize this method for high-risk pediatric patients, but the toxicity of cidofovir therapy has led many to avoid this approach. A study evaluating preemptive therapy with CMX001 (brincidofovir) in children with asymptomatic DNAemia may provide future options in high-risk patients. However, studies are needed to determine the optimal screening procedure with respect to specimen (nasopharyngeal, oral, stool, blood), number of sites, and frequency, since these have not been defined in controlled trials. Routine screening is not warranted in patients at low or moderate risk for HAdV disease [58]. The role of pre-transplant screening is not established, although it may possibly be effective in predicting post-transplant HAdV complications [59].

Infection control

HAdV transmission can occur within inpatient and outpatient environments, owing to the hardy nature of its non-enveloped viral structure that is resistant to many cleaning agents. Small outbreaks have been reported in transplant and hematology units [27].

Table 93.3 Treatment options for probable and proven disease by human adenovirus, polyomavirus, and parvovirus B19 in HCT patients

Virus	First line	Alternative(s)	Comments
HAdV	Reduce immunosuppression if possible AND Cidofovir IV 5 mg/kg once weekly for 2–3 weeks, then every other week	1. Cidofovir IV 1 mg/kg three times weekly 2. Multiviral or HAdV-specific T cells (adoptive therapy), preferably within clinical trials	• Cidofovir has significant renal and marrow toxicity, so prophylactic measures need to be taken, such as hyperhydration, oral probenicid, and discontinuing other nephrotoxic co-medications, if possible • CMX001 may be an alternative after approval by health authorities
BKPyV	Hemorrhagic cystitis: Supportive care ↓ Immunosuppression if possible BKPyV-associated nephropathy: ↓ Immunosuppression if possible	Hemorrhagic cystitis: Cidofovir 0.25–5.0 mg/kg IV once weekly with or without probenicid IVIg 0.4 g/kg for 5 days BKPyV-associated nephropathy: Cidofovir 0.5–5 mg/kg IV once weekly	• Supportive care may include analgesics, spasmolytics, hydration, bladder irrigation, urologic treatment including local hemostasis, clot evacuation, ureteric stenting, nephrostoma. • Decreases in immunosuppression should be considered carefully in patients at risk for GVHD • Other not validated adjunct therapy includes levofloxacin, leflunomide, and possibly MTOR inhibitors • CMX001 may be an alternative after approval by health authorities
JCPyV	Progressive multifocal leukoencephalopathy: ↓ Immunosuppression if possible Rarely hemorrhagic cystitis: see BKPyV	None	• Therapy PML is limited, and no current antiviral options have shown any benefit, including cidofovir, IV immunoglobulins, serotonin uptake inhibitors, and/or mefloquine • CMX001 may be an alternative after approval by health authorities
MCPyV	Merkel cell carcinoma: Surgical resection	Chemotherapy	• No current antivirals are known to be effective against MCPyV carcinoma as a non-replicative pathology
HPVB19	Pure red cell aplasia: Intravenous immunoglobulins 0.4 mg/kg over a 5–10-day course OR Intravenous immunoglobulins 1–2 g/kg/day for 2–5 days	↓ Immunosuppression if possible	• Most IVIg formulations have sufficient antibodies to be effective against pure red cell aplasia • IVIg should be considered in other invasive illnesses associated with human parvovirus B19

HAdV, human adenovirus; PyV, polyomavirus; HPVB19, human parvovirus B19; CBT, cord transplant; GVHD, graft-versus-host disease; IV, intravenous; IVIg, intravenous immunoglobulin; TCD, T-cell-depleted transplantation;

Current recommendations require all patients with respiratory tract infection to be placed under contact and droplet precautions. HCT patients incontinent of stool and children wearing diapers should also be placed under contact precautions for the duration of their illness [60]. Inactivation of HAdV virions by routine cleaning procedures in HCT is largely undefined. In vitro studies comparing different surface-active substances suggest that povidone-iodine derivatives were more active, whereas low alcohol- or isopropanol-based disinfection methods were largely ineffective [61,62].

Human polyomaviruses

Human polyomavirus (HPyV) infections currently encompass more than 12 different species, all of which belong to the genus *Polyomavirus* within the family *Polyomaviridae* (Table 93.4) [63]. Serologic studies indicate that from 30% to more than 90% of the general population have been exposed to the different HPyVs, frequently during childhood [63]. It is thought that the lack of specific symptoms or signs linked to primary infection with any of the HPyV reflects either a subclinical course or an inconspicuous "flu-like" presentation shared with other viral infections [64]. The major mode of HPyV transmission is currently unresolved, but in addition to direct person-to-person contact, exposure to infectious body secretions, contaminated surfaces, sewage, or food items have been postulated as mechanisms for primary infection [65,66]. Approximately 5–40% of healthy blood donors asymptomatically shed BKPyV and JCPyV into the urine [67,68]. Similarly, other HPyVs such as Karolinska Institute PyV (KIPyV) and Washington University PyV (WUPyV) [69], Merkel cell PyV (MCPyV) [70], *Trichodysplasia spinulosa* PyV (TSPyV) [71], and several of the newer HPyVs [72] can be detected in asymptomatic individuals. The role of transfusion and organ transplantation is unresolved, although donor kidneys as the major site of BKPyV persistence are strongly implicated in PyV-associated nephropathy after kidney transplantation [73].

Epidemiology

HPyVs appear to be well adapted to the healthy human host seem to require significant cofactors for developing disease [64]. Indeed, where identified, HPyV-associated disease occurred almost exclusively in individuals with impaired immune functions, including those undergoing HCT (Table 93.4). In immunocompromised patients, the detection rates for most HPyVs seem to be higher than in immunocompetent individuals. Presumably, asymptomatic viral replication is a consequence of less stringent immune control, and is associated with an increased risk of progression to disease for some HPyVs. For BKPyV, the frequency of urinary shedding increases from <10% to 60–80% in patients undergoing HCT, typically occurring after Herpes simplex virus and before cytomegalovirus (CMV) reactivation [74]. In parallel, urine BKPyV loads increase substantially from <3 $\log_{10}$ copies (cp)/mL to >7 $\log_{10}$ cp/mL [75–78]. Interestingly, urinary JCPyV shedding is fairly high in immunocompetent individuals [67] and does not increase dramatically in most immunodeficient patients, suggesting significant differences between these two HPyVs [30,65,74]. KIPyV and WUPyV have been detected in 1–11% of respiratory secretions, and are generally higher in children and in HCT patients compared with respective controls [79–81]. KIPyV was significantly more frequent among HCT recipients (17.8% vs. 5.1%, $p = 0.01$) [82]. Overall, the epidemiologic data for the newer HPyVs in HCT are still incomplete.

Virologic aspects

HPyVs are small, non-enveloped virions of 45nm diameter that show remarkable resistance to inactivation. Their circular double-stranded DNA genome of only ~5100bp does not encode a viral DNA polymerase, nucleoside kinase, or protease, and hence lacks classic antiviral targets. HPyV genomes share a high degree of homology ranging from 50 to 80% at the nucleic acid level [72]. Such homology, and also genotype and strain variation, need to be taken into account when developing, interpreting, and revising diagnostic NAT and in situ hybridization assays for specific HPyVs [83–85].

Table 93.4 Human polyomavirus and disease

HPyV, human polyomavirus; PyV, polyomavirus.

HPyV-specific antibody responses are mainly directed against the VP1 protein forming the outer shell of virions and include binding and neutralizing antibody activities [86,87]. Increases in HPyV-specific antibody levels have been seen in individuals with impaired T-cell responses, increasing viral loads, and HPyV disease, suggesting that they are a marker of recent exposure and presumably derive from memory B cells [86–88]. Cellular immune responses against HPyVs have only been explored for BK-, JC-, and MCPyV [89–93]. Compared with T-cell responses directed against CMV or Epstein–Barr virus, BKPyV- and JCPyV-specific responses are at least 10–50-fold lower in blood, thereby limiting their routine clinical predictive use without prior expansion [92,93].

Diagnostic methods

Diagnosis of HPyV infection, replication, and disease is similar to that for other latent viruses (Table 93.1). HPyV replication is commonly diagnosed by quantitative NAT, whereas direct antigen detection (DAD) and virus isolation by cell culture (VIC) are not routinely used in clinical practice. HPyV NAT can be performed on urine, plasma/serum, blood, stool, CSF, and tissue samples. Qualitative NAT is not considered informative and is discouraged. (Semi-)quantitative NAT is the method of choice and HPyV loads in urine, blood, plasma or serum, and CSF have been proposed as a marker of risk, organ involvement, and outcome.

Proven HPyV disease is commonly diagnosed by immunohistochemistry for LTag as the key diagnostic technique. Staining for VP1 has also been used, but is typically negative in non-replicative HPyV pathology such as Merkel cell carcinoma. In situ hybridization is used in some centers, but determination of assay specificity is needed. Similar to solid organ transplantation [31], testing for HPyV-specific humoral or cellular immune responses currently has curently no role in the clinical evaluation and management of HCT patients.

Clinical manifestations

Proven HPyV disease has been defined for few species [64], namely BKPyV (nephropathy, hemorrhagic cystitis, ureteric stenosis) [68], JCPyV (progressive multifocal leukoencephalopathy, nephropathy) [30], MCPyV (Merkel cell carcinoma) [70], and TsPyV (*Trichodysplasia spinulosa*) [71]. For two, KIPyV and WUPyV, an association with respiratory tract infectious disease has been proposed, but histopathologic proof is only emerging [69].

Renourinary HPyV disease

PyV-associated hemorrhagic cystitis (PyVHC) occurs in 5–15% of allogeneic HCT patients, typically after engraftment, and is linked to high urine BKPyV loads [94]. Other HPyV have no role in PyVHC with the rare exception of JCPyV. As most adult and pediatric PyVHC patients are BKPyV seropositive prior to HCT [94,95], reactivation has been postulated as the major source BKPyV replication. However, some pediatric cases of PyVHC after HCT may result from (re)infection of children with low or undetectable BKPyV-IgG antibodies [78].

The pathogenesis of PyVHC has been suggested to result from a sequence of cooperating events [96,97] (Figure 93.3). First, subclinical injury of the bladder mucosa occurs as a result of urotoxic conditioning protocols used prior to HCT. Then, during the aplastic window, uncontrolled BKPyV replication in urothelial cells may cause denudation of the partly damaged bladder mucosa, and result in urine leakage, and hemorrhagic inflammation, which is exacerbated following engraftment of the allogeneic stem cells [64,97]. The inflammatory response may also be driven by innate immune signals to cytopathic denudation and failure [64], with or without contribution of overshooting responses of BKPyV-specific T cells [93].

The clinical diagnosis of virus-associated HC requires the triad of (1) clinical signs of cystitis, (2) macrohematuria (≥grade II), and (3) significant urine viral loads (Table 93.2). For BKPyV, urine loads are typically >7 $\log_{10}$ cp/mL, but may be lower for more pathogenic viruses such as HAdV [64,98] (see above). In addition, other etiologies should be excluded (Table 93.2). Detection of BKPyV in blood has been associated with a higher specificity of PyVHC after allogeneic HCT, especially when serum BKPyV loads exceed 4 $\log_{10}$ cp/mL [78,98–100].

High urine BKPyV loads, alone, even if together with macrohematuria, are not sufficient for a case definition of HC. Cystitis symptoms may range from low-grade urgency to completely immobilizing pain requiring hospitalization, intensive nursing efforts, and advanced pain management, with significant healthcare costs [101]. Low platelet counts and/or human herpes virus-6 viremia [102] have also been linked to PyVHC [100]. Imaging by ultrasound at the bedside is the most valuable diagnostic measure showing thickened bladder walls and occasionally ureteral involvement and hydronephrossis, whereas magnetic resonance imaging (MRI), or contrast-enhancing computed tomography (caution with renal toxicity of contrast) is less frequenty used. Biopsies are rarely taken because of the risk of excessive bleeding.

The risk factors of BKPyV-associated HC vary in different studies and eras of HCT, but most consistently, myeloablative conditioning, unrelated or mismatched donors, and the use of cyclophosphamide, busulfan, total body irradiation, and lymphocyte depletion have been reported [41,98,100,103–105]. More recently, cord blood HCT has emerged as a risk factor, suggesting that impaired T-cell immunity plays an important role [93,98]. GVHD is a risk factor due to immunosuppressive treatment, and infrequently its involvement of the bladder can be an alternative or concurrent diagnosis [43,106]. In addition to anemia and bacterial infection, BKPyV-associated HC can be complicated by obstructive renal failure with hydronephrosis and serum creatinine increases due to obstructive blot clots. In such cases, ultrasound evaluation may help to evaluate the patients for ureteral involvement and stenosis.

PyV-associated nephropathy (PyVAN) is rarely diagnosed after allogeneic HCT [92,107–111] compared with rates of 8% (95% confidence interval 1–15%) in kidney transplant patients [112]. Unlike HAdV-associated interstitial nephritis after HCT, HC may not be a precursor diagnosis to PyVAN [110,111]. The diagnosis of PyVAN should be suspected in all HCT patients with late-onset progressive renal failure [111]. Potential risk factors are insufficient T-cell responses or impaired recovery as the result of intense immunosuppression for GVHD, exposure to lymphocyte-depleting antibody therapies, and possibly cord blood HCT [109,110]. In pediatric patients, primary BKPyV exposure may be the cause of PyVAN after autologous HCT [108].

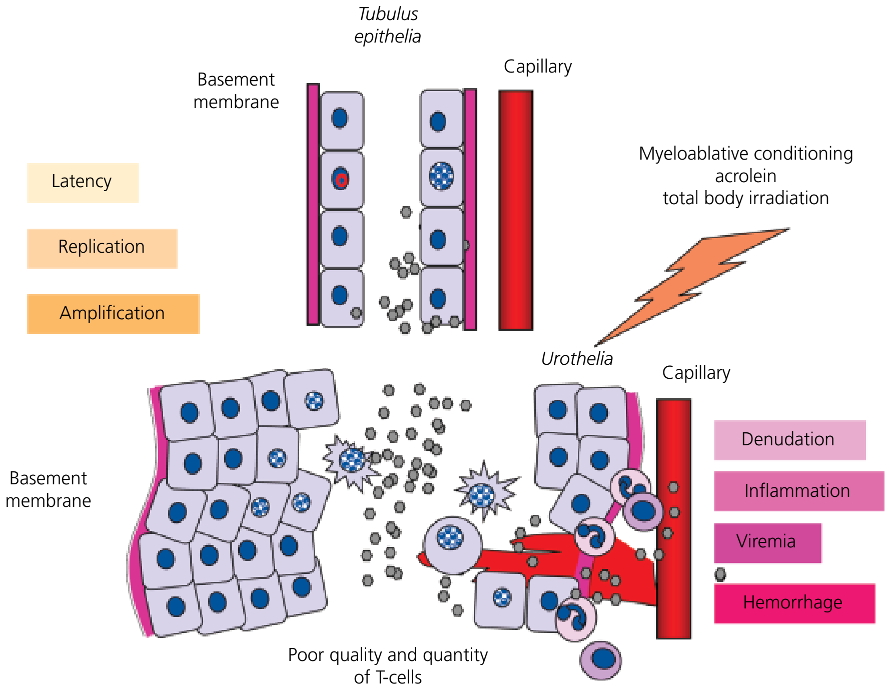

Figure 93.3 Polyomavirus-associated hemorrhagic cystitis after HCT. Source: adapted from Hirsch 2010 [64].

The differential diagnosis of PyVAN includes a variety of partly additive nephrotoxic insults from conditioning, immunosuppressive, antibiotic, antifungal, and antiviral drugs used during HCT. Calcineurin inhibitor toxicity is an important differential diagnosis of elevated creatinine and improvement of renal function following immunosuppression reduction has been interpreted as confirmative evidence. However, undiagnosed PyVAN is also likely to improve with reduced immunosuppression, suggesting that PyVAN frequency may be underestimated in HCT. Proven PyVAN requires renal biopsies demonstrating cytopathic changes of renal tubular epithelial cells with intranuclear inclusions and corresponding immunohistochemistry for large T-antigen [111]. When examined in patients with PyVAN, BKPyV in the blood is universally positive [109–111]. Therefore, in the absence of HC and other reasons for renal failure, plasma BKPyV loads may be a useful first indicator of PyVAN in allogeneic HCT patients. However, universal screening for BKPyV replication has not been evaluated in prospective trials and is currently not indicated in all HCT patients.

Ureteric stenosis after HCT is a rare complication after HCT and may be related to BKPyV-associated HC. This complication often presents as unilateral or bilateral hydronephrosis on ultrasound. In contrast to blood clot-mediated obstructive HC, proliferative changes of the ureteric ostium have been described [113,114], possibly subsequent to BKPyV infection as seen after kidney transplantation [115]. BKPyV viruria or viremia is not useful in this diagnosis, but histopathology of the resected tissues can be helpful in ruling out other diagnoses such as malignancies.

Neurologic HPyV disease

Progressive multifocal leukoencephalopathy (PML) is a frequently fatal demyelinating disease caused by JCPyV in immunodeficient patients [30]. Uncontrolled cytopathic JCPyV replication in myelin-producing oligodendrocytes impairs neuronal function and causes (multi)focal neurologic deficits. Recent studies suggest that adjacent astrocytes and gray matter neurons, and specifically granule cell neurons of the cerebellum, might also be affected [30]. PML was first recognized as a distinct pathologic entity in patients with hematologic malignancies such chronic lymphatic leukemia or diverse types of lymphomas long before the era of HCT, suggesting an important role of profound and chronic immune dysfunction affecting both T- and B-cell subsets [116]. PML is seen in other immunocompromised populations, such as HIV-AIDS patients [117] and solid organ transplant recipients [118], and has been reported as a complication of natalizumab, a monoclonal antibody used in multiple sclerosis, and rituximab [30]. The rates of PML in allogeneic HCT patients are not well defined and may be lower than the rate of 0.1% estimated in solid organ transplant patients [118]. When reported, PML occurred in the first year after HCT, ranging from 1 to 20 months, and was frequently fatal [119,120].

PML should be suspected in immunocompromised patients showing progressive focal neurologic deficits and compatible radiologic findings on MRI (possible PML). Neurologic findings associated with PML include motor and sensory deficits, ataxia, and alterations of memory, speech, and mental status. MRI demonstrates enhanced signals in fluid-attenuated inversion recovery and T2-weighted images, but hypointense signals in T1-weighted imaging [121]. Detection of JCPyV DNA by NAT of CSF is required for laboratory- or virologically confirmed PML (probable disease). The sensitivity of clinical JCPyV-NAT assays is critical and should reach <50 cp/mL [83]. In cases with undetectable JCPyV DNA in CSF, or other suspected etiologies, stereotactic brain biopsy is indicated, which permits the histopathologic diagnosis of proven disease showing typical cytopathic changes of oligodendrocytes and positive staining for LTag [30]. Unlike BKPyV-associated HC and nephropathy, JCPyV DNA may not be detectable in blood in patients with PML and cannot reliably be used for screening and monitoring [30]. The differential diagnosis includes calcineurin inhibitor-associated leukencephalopathy and viral infections of the CNS such as HPVB19, EBV, CMV, and HHV6. Other HPyVs are usually not detectable in CSF [122], but BKPyV has been implicated in a similar clinical presentation in non-HCT patients [68,123].

Other HPyV-associated diseases

Respiratory tract infectious disease (RTID) in HCT patients has been investigated for KIPyV and WUPyV as these viruses were first detected in respiratory specimens [69]. In a large prospective study of 222 HCT patients, the cumulative detection rate of KIPyV and WUPyV was estimated as 26 and 8%, respectively, in the first year after transplantation [79]. KIPyV- and WUPyV-positive patients were typically younger (age <20 years) and were more likely to have had sputum production and wheezing in the preceding 1–4 weeks. These viruses were not associated with GVHD, lymphopenia, hospitalization or death. However, co-infection of other respiratory and latent viral infections was common [124]. Semiquantitative KIPyV and WUPyV loads have been thought to help differentiate RTID from GI sites of replication [124], and higher KIPyV loads have been reported in bronchoalveolar lavage (BAL) of symptomatic children with leukemia and in those undergoing HCT [80]. The link between KIPyV and WUPyV severe RTID is largely missing, and to date histologic proof of invasive disease is only emerging in case reports [125,126]. In addition, BKPyV-associated pneumonitis has been described in single HCT case reports [127,128].

Gastrointestinal disease including colitis has not been proven by histopathology, but detection of BKPyV, JCPyV, KIPyV, WUPyV, HPyV9, HPyV10, and HPyV12 in fecal specimens has been suggested to indicate replication in this compartment [82,129,130]. However, contamination of fecal specimens from urine in patients with hemorrhagic cystitis [129] or from swallowed sputum confound the interpretation of HPyV detected from this site [124].

Skin diseases associated with HPyV include proliferative changes and non-melanoma skin cancer [64,131]. These entities are increased in immunodeficient patients, including in solid organ transplant and HCT recipients, compared with the general population [64]. Merkel cell carcinoma is a cutaneous malignancy that shows some histologic features of Merkel cells transmitting the sensation of touch [70]. In recent decades, Merkel cell carcinoma has increased from 0.1 to 0.9% in registry studies, and the risk factors for Merkel cell carcinoma are older age, exposure to sunlight, and immunodeficiency such as chronic lymphatic leukemia, HIV-AIDS, and solid organ transplantation [132]. There are few cases linked to hematologic diseases and HCT [133–135]. Clinically, patients develop exophytic growths on their skin (Figure 93.4), but aggressive spread to lymph nodes, visceral organs, bone, and marrow is linked to a high fatality rate of more than 50% within 1–2 years. MCPyV has been detected in more than 80% of Merkel cell carcinomas, with critical alterations of the viral genomes and small T-antigen as oncogenic driver [70]. Since MCPyV is widely detected on skin of asymptomatic healthy individuals, the pathogenesis presumably involves additional oncogenic events of virus, spreading, and host cell that lead to clinical disease in immunodeficient individuals. Serologic studies indicate higher antibody titers in patients with Merkel cell carcinoma compared with healthy individuals, suggesting that at some point, (re-)exposure to viral antigen must have occurred prior to the disease [87].

Trichodysplasia spinulosa is proliferative skin disease of immunocompromised patients, which has led to the identification and cloning of TSPyV [136,137]. Other terms used have been *pilomatrix dysplasia* of immune suppression, or cyclosporine-induced folliculodystrophy. The clinical diagnosis is made by characteristic skin changes occurring in an immunocompromised patients. Typically, follicular papules are seen with outright spines in the face centering around the nose and the ears, and less frequently on the rest of the body (Figure 93.5). Non-scaring alopecia of the eyebrows may develop, replacing the hairs by hyperkeratotic protrusions. The affected skin areas thicken with the duration of the disease.

Histologically, the hair follicle is enlarged through proliferative changes replacing normal corneocytes. The changes are presumably caused by TSPyV causing proliferative alterations of the inner root sheath cells, in which immunohistochemistry for VP1 capsid is positive and PyV particles can be seen by electron microscopy [71,136,137]. In a thorough review, 25 trichodysplasia spinulosa cases were summarized and included eight cases with hematologic malignancies [71]. Trichodysplasia spinulosa is likely underdiagnosed in HST patients, especially those with chronic GVHD.

Treatment

The treatment of HPyV replication and disease represents a formidable challenge given the lack of specific antivirals (Table 93.3). To date, there have been no randomized controlled trials demonstrating clinical efficacy of any antiviral in the treatment of HPyV diseases. Although various case series suggest that intravenous cidofovir may be an option for therapy, the role of spontaneous HPyV-specific immune recovery cannot be excluded as the true etiology of improved outcomes. Given the limited in vitro efficacy of cidofovir, other agents such as CMX001, fluoroquinolones, leflunomide, and MTOR (mammalian target of rapamycin) inhibitors might have a beneficial effect in prophylaxis. Unfortunately, preliminary data with levofloxacin suggest only a limited role in prophylaxis, with little effect on HC symptoms [138]. CMX001 may provide a better ratio of antiviral activity over drug toxicity [139] and could be a potential future prophylaxis or treatment option, pending ongoing clinical studies [140].

Reducing immunosuppressive therapy needs to be considered as a primary treatment modality for all HPyV diseases in HCT patients. Unfortunately, increased risk for local and systemic immunologic damage from acute or chronic GVHD in HCT often hampers immunosuppression reduction. Adoptive T-cell transfer may be an interesting future option that is currently being explored [53].

BKPyV-associated HC is primarily treated symptomatically through pain management, spasmolytics, hydration and forced diuresis, and intravesical catheterization for bladder irrigation to reduce obstructive clots. More complicated cases require urologic clot evacuation, local hemostasis with coagulation factors, epsilon-aminocaproic acid, selective embolization, and even cystectomy. *Blood* products should be substituted as needed to counter anemia, low platelet counts, and possibly clotting factors. In a systematic review, the tremendous challenge of HC was acknowledged and the level of evidence for any single treatment was very low [141]. Some centers use intravenous cidofovir or intravesical cidofovir as off-label antiviral adjuncts, but results are mixed and overall disappointing with respect to response time and efficacy on viral loads [78,98,142–144].

BKPyV-associated nephropathy is primarily treated by reducing immunosuppression, but the role of low-dose intravenous cidofovir and switching immunosuppressive drugs to leflunomide and sirolimus is controversial [110,111].

Ureteric stenosis is primarily treated by urologic intervention following cystoscopy, and involves stenting or nephrostoma for the acute treatment and surgical resection for complicated cases.

Progressive multifocal leukoencephalopathy does not respond to currently available antiviral agents, and cidofovir therapy does not limit disease progression in other immunocompromised populations [30]. Suggestions that CMX001 might have some efficacy in vitro [145] and in vivo (H.H. Hirsch, and Chimerix Inc., personal communication), but need to be replicated in appropriate clinical studies.

Merkel cell carcinoma is primarily treated by early surgical resection and chemotherapy for metastizing cases with generally poor outcome. Trichodysplasia spinulos*a* can be treated by reduced immunosuppression and possibly topical 1%–3% cidofovir [137].

For HPyV-associated RTID, no recommendations can be made for severe cases; possibly intravenous immunoglobulins could be considered owing to their immunomodulating and neutralizing potential. In summary, specific antivirals would have an important role by extending the window until virus-specific immune responses have recovered.

Prevention

Prevention of HPyV replication and disease in HCT patients is a difficult task given the ubiquitous presence of HPyVs in healthy individuals and the lack of clinically validated antivirals. As HPyV detection rates and viral load levels increase in immunocompromised patients including those undergoing conditioning and HCT, exposure to endogenous HPyV infection cannot be prevented. However, exogenous exposure may be underestimated. The shedding of BKPyV and other HPyV at levels >7 $\log_{10}$ cp/mL urine or feces for several weeks and the fact that HPyVs are fairly resistant to inactivation similarly to other non-enveloped viruses [61,62,146,147] renders transmission from one immunocompromised patient to another via healthcare workers, nursing facilities, and toilet equipment a plausible scenario. Although most individuals are likely to have HPyV-specific antibodies, this may not be so for all HPyVs and their serotypes, particularly in younger children [78].

Screening of HCT patients for high-level BKPyV replication in urine and blood occurs at some centers, but generally is not recommended. Decisions regarding administration of preemptive cidofovir or other presumed antivirals such as leflunomide, fluoroquinolones, or intravenous immunoglobulins to patients with BKPyV viremia will requires careful randomized studies to determine the risk–benefit/efficacy ratio given significant concerns over toxicity issues, costs, and the development of resistance.

It is possible that cidofovir, leflunomide, and MTOR inhibitors might have a beneficial effect as prophylaxis, but none have been studied for this purpose. Data suggest that fluoroquinolones may have a role in prophylaxis, but randomized trials needed to confirm these results have failed in kidney transplant recipients [138,148,149]. However, a large prophylaxis study of lipid cidofovir conjugate CMX001 on CMV replication in HCT may provide a future option for either treatment or prevention [140,150].

Human parvovirus

The major human pathogen in the *Parvovirus* family is human parvovirus B19 (HPVB19). HPVB19 is the cause of erythema infectiosum (Fifth disease), a self-limited infection of childhood characterized by fever, fatigue, myalgias, a lace-like reticular rash, and a "slapped-cheek" appearance. The predominant manifestation in adults is acute symmetrical arthropathy that can mimic rheumatoid arthritis and other rheumatologic diseases. HPVB19 is also the cause of transient aplastic crisis in patients with hemolytic conditions, such as sickle cell disease [151]. HPVB19 replication is rarely detected in HCT recipients, but can lead to a number of clinically significant complications, particularly in cells of the erythroid lineage [152].

Epidemiology

HPVB19 is present throughout the world and studies demonstrate increasing seroprevalance with age, as approximately 5–20% of children, 30–60% of young adults, and over 75–90% of elderly persons have evidence of prior infection [153–155]. Individuals who work closely with children, have a history of intravenous drug abuse or HIV, or who are otherwise immunocompromised may be more likely to be seropositive [156,157]. It is thought that seronegativity may increase the risk of complications in HCT recipients, but incidence rates of HPVB19 DNAemia and disease are difficult to calculate owing to the rarity of the disease in this population [158,159].

HPVB19 is thought to be transmitted through three primary pathways: respiratory droplets, blood products, and from mother to fetus (vertical transmission) during acute maternal parvovirus infection. During primary DNAemia, HPVB19 leads to pulmonary shedding and respiratory droplets that can lead to transmission to close contacts. Transmission also occurs in susceptible patients through transfusion of blood components or transplantation. These are rare events with most single-component transfusions, as less than 1% of blood donors have detectable viral DNA [160]. Plasma derivatives, which are made from multiple units, are more likely to have detectable virus [161] and these plasma products undergo NAT routinely for HPVB19 DNA. Finally, in susceptible patients undergoing transplantation, the donor stem-cell product can also be the source of transmission [162].

Virologic aspects

Parvoviruses are small, non-enveloped, single-stranded DNA viruses of the family *Parvoviridae*. Although HPVB19 is the major human pathogen, two other *Parvoviridae*, parvovirus 4 (PAV4) and adeno-associated virus (AAV), have been detected in humans. To date, neither PAV4 nor AAV has been linked to disease manifestations in HCT [163,164].

HPVB19 primarily infects erythroid progenitor cells, which allow for viral propagation [165]. HPVB19 binds as its host receptor the common blood group P antigen [166]. The virus leads to cell death through apoptosis mediated by non-structural proteins such as NS1 [167]. Immunity to HPVB19 is thought to be primarily humoral; neutralizing antibodies to the capsid proteins play a major role in host defense [168]. Most immunocompromised patients have a marked decrement in antibody production, must contend with recurrent DNAemia, and are more likely to develop complications [159,168]. Seronegative HCT recipients may be at the highest risk for clinical disease, as experimental studies have shown that recipient, not donor, cells likely provide the majority of protection from post-transplant replication [169].

Diagnostics

The reliability of serology in the diagnosis of acute parvovirus infections in HCT recipients is limited owing to poor antibody production [168]. In a review of 24 HCT recipients with HPVB19, only 40% had evidence of serum IgM at the onset of disease and only 33% IgG [159]. Most cases of severe disease are defined in part by their lack of appropriate antibody responses.

Detection of viral DNA has become the most reliable way to confirm the diagnosis. High levels of virus can usually be found in peripheral blood and bone marrow samples of HCT recipients with disease [151]. The high level of sensitivity of PCR means that low-level HPVB19 DNA can be detected in those without evidence of clinical disease [170]. The mere presence of HPVB19 DNA in serum needs to be interpreted in conjunction with the clinical picture, particularly in pediatric transplant patients. In one study, for example, 30% of pediatric allogeneic transplant patients had detectable HPVB19 DNA, but none had clinical sequelae [164]. Evidence of PCR detection from biopsy samples may be needed to confirm tissue-invasive disease, but positive results, principally low-level values, do not by themselves define organ involvement [171].

Biopsy or other pathologic samples can increase the ability to make the diagnosis of HPVB19 disease. The most important site is the bone marrow, where classically there is an absence of erythroid precursors, and giant pronormoblasts with intranuclear inclusions and cytoplasmic vacuolation [172]. Biopsies from other sites including liver and cardiac tissue can also be evaluated for HPVB19 DNA in appropriate clinical situations.

Parvovirus B19 disease

Pure red cell aplasia

The true incidence of HPVB19-associated pure red cell aplasia is unknown among HCT recipients, but regardless, it is a rare post-transplant complication [159]. In these patients, recovery of B-cell function is often months after transplantation [173], and immunoglobulin concentrations can take up to 1 year to recover fully [174]. Antibody production may also be negatively affected by common post-transplant events, such as the use of immunosuppression, other infections [175], antithymocyte globulin (ATG) [176], and ongoing therapy for acute and chronic GVHD. Since antibody production is critical to clearance of DNAemia, HCT patients can develop chronic HPVB19 replication and pure red cell aplasia.

Patients with pure red cell aplasia may present initially with fever and rash, but others are asymptomatic and present only after developing anemia. Clinical signs of anemia, such as fatigue, pallor, and dyspnea, follow about 1 week after infection; rarely do patients present with classic arthropathy [159]. A high index of suspicion is needed to make the diagnosis as these symptoms and the presence of anemia are common during the post-transplant period. *Blood* smears in these patients will demonstrate normochromic, normocytic anemia, but classically with a reduction in reticulocytes. In some cases, patients may present with additional thrombocytopenia or neutropenia. Pathologic review of bone marrow demonstrates a lack of erythroid precursors and increased numbers of giant pronormoblasts that may have intranuclear inclusions and cytoplasmic vacuolation [172].

Other hematologic disorders

HPVB19 has been associated with thrombocytopenia and neutropenia in HCT recipients [152,159,162]. Although thrombocytopenia and granulocytopenia are rarely seen as isolated phenomenon in other populations, these cytopenias in HCT are universally reported with associated erythroid abnormalities. Rarely, HPVB19 has been implicated in the development of pancytopenia and marrow failure in HCT recipients [177]. Hemophagocytic syndrome has been described as a complication of HPVB19 in other immunocompromised populations [178].

Myocarditis

Myocarditis is an unusual complication of HPVB19 in transplant patients. However, in a large retrospective review of reported cases, myocarditis was seen more frequently in HCT patients (12.5%) than in other immunosuppressed populations [159]. It is thought that the target of the virus is endothelial cells, and that viral-mediated microcirculatory dysfunction leads to myocardial damage [179]. Although detection of HPVB19 viral genomes in patients with myocarditis suggests a direct link between HPBV19 replication and disease [180], it is unknown if the virus plays more of a bystander role in the development of myocarditis [171].

Other reported complications

HPVB19 pneumonia has been detailed [181], but viral shedding in the upper and lower respiratory tract during acute infection [182] means that direct associations must be considered cautiously and other pathogens ruled out before considering HPVB19 as the primary etiology. Patients with HPVB19 may have elevated liver enzymes during acute infection, and acute HPVB19 hepatitis has been described in HCT [183]. Cases of HPVB19 encephalopathy have also been reported sporadically [184,185].

Treatment

HCT recipients should be given therapy if HPVB19 is diagnosed as the causative agent for symptoms; treatment is often considered for patients with documented red cell aplasia while awaiting confirmatory testing. The mainstays of treatment are the use of IVIg and, if possible, modifications in immunosuppressive therapy (Table 93.3). A study of samples in the United States and Europe demonstrated that most IVIg preparations contain sufficient antibodies for HPVB19 neutralization [186]. Published data indicate that short-term IVIg can ameliorate anemia in pure red cell aplasia and has been shown to be effective as a therapeutic approach to patients with organ involvement [158,159]. Decreasing immunosuppression is an important adjunct to treatment with IVIg, but this is not always possible in HCT recipients.

Dosing of IVIg has been recommended from 0.4mg/kg body weight given over a 5–10-day course [187] to 1–2g/kg/day for 2–5 days [188]. In a retrospective study of immunocompromised patients [158], patients received a mean of 2.8 IVIg courses and a higher mean starting dose of 2.3g/kg; 38% had reductions in immunosuppression in conjunction with their treatment. Initial response was excellent with a total of over 90% recovering their counts after the first dose. Unfortunately, relapse occurred in 31% of patients at a mean of 4.3 months. A response to IVIg at 12 months was associated in multivariate analysis with an 89% reduction in mortality from HPVB19 disease [158].

Prevention

The relative rareness of HPVB19 disease in HCT limits the use of widespread strategies to prevent exposure beyond standard infection control measures. Baseline serologic testing is not currently recommended for patients undergoing HCT or their donors, and post-transplant screening is not currently recommended for prevention [189]. Although prophylaxis is not recommended, the routine use of IVIg in some populations during the post-transplant period has been hypothesized to decrease overall risk [190].

It is important to consider isolation for HCT recipients with ongoing HPVB19 replication, as HPVB19 has been associated with nosocomial outbreaks [191]. In addition to standard precautions, droplet precautions are recommended for HCT recipients diagnosed with HPVB19 [192]. Pregnant healthcare workers should be informed of potential risks of HPVB19 exposure, and seronegative persons should avoid taking care of these patients [192]. Recommendations are not clear for HCT patients who have improved symptoms but develop prolonged DNAemia, as it is unclear how long immunocompromised patients remain infectious. Such cases should be discussed with local infectious diseases and infection control professionals.

CHAPTER 94

Gastrointestinal and Hepatic Complications

David M. Hockenbery[1], **Simone I. Strasser**[2] **and George B. McDonald**[1]

Introduction

The frequency and severity of intestinal and liver complications of hematopoietic cell transplantation (HCT) have declined steeply over the last decade, with some complications disappearing completely, for example, herpes simplex virus (HSV) esophagitis, intramural hematomas, candidal liver abscesses, hyperammonemia, and gastric antral vascular ectasia [1,2]. Fewer patients have severe gut and liver damage from acute graft-versus-host disease (GVHD), as the development of more effective strategies to prevent GVHD has had a marked effect on its clinical presentation. Protracted jaundice is now far less common, as the frequency of sinusoidal liver injury caused by myeloablative regimens has fallen, and prophylaxis with ursodiol has been effective in mitigating cholestatic liver injury [1]. Prophylaxis with antiviral and antifungal drugs has greatly reduced the incidence of the most common gut and liver infections [2]. This chapter mentions now rare complications in an abbreviated way so that the lessons of the past are not completely forgotten. More emphasis is given to problems that are still common, for example, anorexia following conditioning therapy; acute GVHD, protracted acute GVHD, and liver presentations of GVHD; adenovirus, cytomegalovirus, and norovirus infections; and problems in long-term transplant survivors.

Evaluation of intestinal and liver problems before transplant

Ulcers, tumors, and infections in the gastrointestinal tract

In immunocompromised patients, mucosal ulcers may have an infectious etiology [e.g., cytomegalovirus (CMV), HSV, or fungal infection] that requires specific antimicrobial treatment. Thus, symptoms of esophageal pain, heartburn, dysphagia, abdominal pain, nausea, vomiting, and diarrhea should be investigated with endoscopy before HCT, and all intestinal ulcerations healed before the start of conditioning therapy, to avoid major bleeding when platelet counts fall. The goal of pre-HCT therapy in patients with ulcerative colitis or Crohn's disease is to minimize the extent of gross intestinal ulceration to lower the risk of bleeding after HCT and to rule out infections as a cause of colonic ulceration. CMV, *Entamoeba histolytica*, and clostridial infections are causes of colonic ulceration that may mimic inflammatory bowel disease. CMV disease before transplant is associated with a high risk for early CMV disease and death after HCT [3]. Selected patients with ulcerative colitis and Crohn's disease have undergone both allogeneic and autologous HCT without complications of bleeding, perforation, or dissemination of microorganisms [4–6]. Long-term resolution of Crohn's disease has been observed following myeloablative allogeneic HCT, and autologous HCT has also resulted in improvements.

Patients who are to undergo HCT for lymphoma, leukemia in relapse, myeloma, or metastatic breast cancer may have intestinal involvement with malignant cells. Cytoreductive therapy results in necrosis of these cells, which rarely can lead to large intestinal ulcers and perforation. Intra-abdominal abscesses and fistulae should be managed surgically before HCT. Patients over the age of 50 years are at risk for the development of colorectal polyps and cancer; the presence of occult blood in stool specimens from patients over 50 years old should prompt endoscopic evaluation, including colonoscopy.

Diarrhea

Patients with diarrhea should be investigated for organisms that may cause morbidity after HCT (*E. histolytica*, *Strongyloides*, *Giardia lamblia*, *Cryptosporidium,* CMV, rotavirus, norovirus, and adenovirus) [7–11]. Persistent eosinophilia in a patient from an area where parasites are endemic is also an indication for screening for parasitic disease, including helminths, and *Cystoisospora belli*. Specific therapy is available for amebiasis, giardiasis, strongyloidiasis and other helminths, and most coccidia and microsporidia. Many of these opportunistic infections can be refractory to treatment in immunosuppressed patients [12], while restoration of normal immunity after allogeneic HCT can result in clearance [10,13].

Other treatable causes of diarrhea in patients with hematologic malignancies include clostridial infections (*Clostridium difficile*, *C. perfringens*, and *C. septicum*) [14]. The patient who has had previous typhlitis (neutropenic enterocolitis) during neutropenia can present problems if there is persistent fever or tenderness over the cecum. Typhlitis is a syndrome of cecal edema, mucosal friability and ulceration, and fever often associated with polymicrobial sepsis; its cause is usually intestinal infection caused by *C. septicum*. After treatment, the risk of post-HCT typhlitis is no different from that of other patients. Pericolic phlegmons, abscesses, and persistent colitis caused by clostridial infections must be treated before the start of conditioning therapy.

As with Crohn's disease and ulcerative colitis, gut inflammation in patients with immune disorders has been noted to disappear after

successful allografts; examples include refractory celiac disease and a spectrum of pediatric disorders of immune dysregulation — severe combined immunodeficiency (SCID); immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome; interleukin (IL)-10-receptor defect or IL-10 deficiency; chronic granulomatous disease; Wiskott Aldrich syndrome; common variable immune deficiency (CVID) with severe autoimmune problems; X-linked lymphoproliferative disease; X-linked agammaglobulinemia; trisomy 8 mosaicism (Behcet's like); nuclear factor-kappa B (NFκB) essential modulator (NEMO) deficiency; and STAT1 gain-of-function mutations [15,16].

Perianal pain

Transplant candidates are not spared common causes of perianal pain (anal fissure, thrombosed external hemorrhoid), but if a patient is neutropenic, bacterial infection should be suspected until proven otherwise. Most anorectal infections begin in the anal glands deep to the crypts at the dentate line. Inflammation of anal crypts may cause pain in the absence of an abscess. Abscesses tend to originate in the intersphincteric space and may extend into the perianal, ischiorectal, or supralevator space. Extensive supralevator and intersphincteric abscesses may be present without being apparent on external examination, but can be diagnosed by axial computed tomography (CT), magnetic resonance imaging (MRI), or transperineal sonography. Perianal infections must be dealt with before HCT, as extensive tissue necrosis and septicemia may result from uncontrolled infection [17]. Administration of broad-spectrum antibiotics, including anaerobic coverage, is adequate treatment in most cases, with surgical incision and drainage reserved for progressive infections [18]. Proctitis and genital ulcers due to HSV infection, perianal CMV ulcers, and rarely fungal infections may also lead to perianal pain [19].

Liver disease in donors and recipients

Viral hepatitis in allogeneic HCT donors

Hepatitis B and C will be transmitted from viremic donors to transplant recipients [1]. When equally human leukocyte antigen (HLA)-matched donors are available, a donor who is not infected by hepatitis viruses should be selected. If the most suitable donor has chronic hepatitis B or C, however, preventing passage of virus and mitigating the effects of infection in the recipient become priorities. Oral nucleos(t)ide analogs such as entecavir and tenofovir result in rapid hepatitis B virus (HBV) suppression with negligible risk of antiviral resistance and, where possible, should be used to reduce viral load prior to donor hematopoietic cell harvest. However, HBV may persist in donor peripheral blood mononuclear cells despite clearance from serum [20], and the recipient transplanted from an HBsAg-positive, serum HBV DNA-negative donor should receive prophylactic oral antiviral therapy for at least 1 year. Hepatitis B vaccination of HBsAg-negative recipients prior to the start of conditioning therapy may also be beneficial if there is risk of passage of virus from an infected donor. When both donor and recipient are infected by HBV, the recipient should be treated with oral nucleos(t)ide therapy starting prior to conditioning therapy. In this setting, there may also be theoretical reasons to lower the viral load in the donor, for example, if the recipient's HBV is in a latent or occult phase or if donor and recipient HBV differ in genotype.

Occult hepatitis B is the presence of detectable serum HBV DNA in HBsAg-negative individuals. The prevalence of occult hepatitis B varies according to the HBV prevalence in the population, being higher in HBV-endemic countries where rates up to 6–15% in HBsAg negative/anti-HBc-positive blood donors have been reported [21]. Individuals with isolated anti-HBc positivity are more likely than those with both anti-HBc and anti-HBs to have occult hepatitis B. Donors with occult hepatitis B can be used, but if possible the recipient should be vaccinated prior to conditioning therapy and given oral antiviral prophylaxis for up to 1 year after transplant. A donor who is naturally anti-HBc positive may be the preferred donor if the recipient is HBsAg positive or anti-HBc positive, as adoptive transfer of immunity can effect clearance of virus [22].

If a preferred donor is hepatitis C virus (HCV) antibody and RNA positive in serum, HCV will usually be transmitted, and the rate of spontaneous viral clearance from the recipient is likely to be low. If time permits, treatment of the donor with antiviral therapy prior to harvest of donor cells may render cells and serum non-viremic and much less likely to transmit infection. Direct Acting Antiviral (DAA) drugs can clear extrahepatic HCV from donors more quickly than interferon and ribavirin without significant toxic effects on the donor marrow [23,24]. If time does not permit treatment of an HCV-infected donor, the use of HCV-infected hematopoietic cells for an HCV-uninfected recipient is not absolutely contraindicated because new DAAs can provide a virologic cure in the majority of transplant survivors after recovery and immune reconstitution. Therapeutics for HCV treatment are rapidly evolving; we recommend this website for continuously updated information: http://www.hcvguidelines.org. As of 2015, for HCV infection with genotype 1a, 1b, or 4, treatment with one of the following DAA combinations is recommended: Daily fixed-dose combination of ledipasvir and sofosbuvir, or twice daily fixed-dose combination of ombitasvir, paritaprevir, ritonavir and dasabuvir, or daily sofosbuvir plus simeprevir. For infection with genotypes 2, 3, or 5, the preferred regimen is sofosbuvir plus weight-based ribavirin. Monotherapy with a DAA is not recommended regardless of HCV genotype. If HCV is transmitted, the acute phase of HCV infection may cause elevated liver enzymes at 2–3 months post-HCT, after recovery of T-cell function [25]. However, severe hepatitis and fibrosing cholestatic hepatitis have rarely been described after HCT [26]. Overall, outcomes in HCV-infected recipients in 10 years of follow-up are no different from those in transplant recipients without hepatitis C infection [25,27]. In the long term, antiviral treatment should be offered to the recipient who remains with active hepatitis C, as such a patient is at risk for development of cirrhosis and hepatocellular carcinoma [1].

Chronic liver disease in candidates for HCT

Patients with active liver disease, particularly those with severe hepatic fibrosis or cirrhosis, are at increased risk for fatal sinusoidal obstructive syndrome (SOS) (formerly known as venocclusive disease of the liver) following hepatotoxic myeloablative regimens [1]. The presence of cirrhosis may provide a contraindication to any high-dose conditioning regimen because such patients are at risk for fatal sepsis or hepatic decompensation after HCT even if given a reduced-intensity conditioning regimen [28]. Liver biopsy should be considered if there is a clinical suspicion of cirrhosis or extensive fibrosis (for example, in patients with myelofibrosis [29]). There are alternatives to biopsy: 1) Analysis of blood test panels are not recommended because their components are often affected by underlying hematologic disease; and 2) Vibration-controlled transient elastography can be useful in pre-HCT screening for fibrotic liver disease [30,30a,30b]. Patients with fibrotic and necroinflammatory chronic liver disease should be considered for either reduced-intensity or "liver-friendly" myeloablative regimens (see the section Sinusoidal obstruction syndrome).

Hepatitis B-infected HCT recipients are at risk for severe hepatitis flares and fulminant liver failure. In the absence of antiviral prophylaxis, HBV reactivation is common, and fatal fulminant hepatitis develops in approximately 15% [1]. Prophylaxis with oral nucleos(t)ide therapy starting prior to conditioning therapy is therefore recommended for all HBsAg-positive recipients. Occult hepatitis B may also be associated with HBV reactivation, with rates up to 35% seen in recipients with isolated anti-HBc antibodies, particularly during treatment for acute GVHD [31]. Patients born in countries where hepatitis B is endemic need close monitoring for HBV reactivation after HCT, even when pre-HCT blood tests were negative for prior HBV infection [32].

Recent liver dysfunction in candidates for HCT

Patients who come to HCT following recent chemotherapy or radiation therapy may be at risk for unexpected toxicities following myeloablative conditioning regimens, particularly if these therapies have resulted in liver dysfunction. Many chemotherapy drugs cause liver dysfunction either directly (cholestatic injury, hepatocyte necrosis, or sinusoidal damage) or indirectly (cholestasis caused by sepsis or endotoxemia, i.e., cholangitis lenta) [33]. Severe liver injury from recent chemotherapy is uncommon, however. Recent exposure to standard chemotherapy has not been associated with an increased risk of fatal SOS after cyclophosphamide (CY)-based myeloablative regimens, but patients presenting for HCT with persistent jaundice and elevations of aminotransferase enzymes are likely at risk. Liver injury has been associated with prolonged exposure to antimetabolites such as 6-thioguanine and also agents such as imatinib (Gleevec) and newer tyrosine kinase inhibitors. Gemtuzumab ozogamicin (Mylotarg) causes sinusoidal liver injury in 3–15% of patients, thus predisposing to SOS after hepatotoxic myeloablative regimens, particularly if the patient is transplanted within 3 months of high-dose gemtuzumab exposure [1,34].

Fungal liver infections

A search for hepatic fungal infection should be undertaken in patients with tender hepatomegaly, fevers, and abnormal liver enzymes. Diagnosis may be established by sensitive liver imaging (high-resolution CT or MRI) in conjunction with fungal biomarkers such as serology for fungal antigens (galactomannan and glucan assays) and polymerase chain reaction (PCR) or culture of liver biopsy material [35]. Fungal liver infection should be controlled with systemic antifungal agents, with newer agents such as the echinocandins offering reduced toxicity, fewer drug–drug interactions, and a broader range of coverage. Therapy should be continued through HCT until engraftment is established, which can effect the resolution of intractable fungal liver abscesses.

Gall bladder and bile duct stones

HCT candidates with asymptomatic gallstones (incidentally discovered during a CT scan or ultrasound) do not require operative intervention. Patients with symptomatic gall bladder or common duct stones are at significant risk of sepsis after HCT, and consideration should be given to pre-transplant cholecystectomy or an endoscopic biliary procedure.

Iron overload

HCT candidates with diseases such as thalassemia, aplastic anemia, myelodysplastic syndrome, and chronic leukemia or lymphoma may come to HCT with marked hepatic iron overload caused by transfusions, gut hyperabsorption of dietary and medicinal iron, and uncommonly from genetic hemochromatosis. Extreme liver iron content (>12,500 μg per gram dry weight), more accurately assessed by T2* MRI than serum ferritin or transfusion history, has been associated with increased non-relapse mortality post-HCT from cardiac arrhythmias and mold infections [36]. In patients with extreme iron overload, effective pre-HCT chelation therapy improves post-HCT survival. While some studies suggest an association between excess tissue iron stores and regimen-related toxicity, others have failed to demonstrate this. After HCT, severe iron overload has been associated with non-specific liver dysfunction that may respond to erythropoietin-assisted phlebotomy or chelation. In most patients, the quantitation of tissue iron stores and consideration of iron removal can be deferred until after recovery from HCT [37].

Problems from transplant through the first year

Nausea, vomiting, and anorexia

Studies of gastric emptying and myeloelectric activity in HCT patients have shown that symptoms of nausea and vomiting are frequently accompanied by retention of radionuclide meals and disordered electrical activity [38–40]. Promotility agents such as metoclopramide, domperidone, and low-dose erythromycin are occasionally useful, but in patients with persistent symptoms, endoscopic biopsies to look for the underlying cause of symptoms should precede protracted anti-emetic and promotility therapy.

Conditioning therapy

Mucositis caused by conditioning therapy leads to oral mucosal swelling, pain, and, in severe cases, sloughing of pharyngeal and esophageal epithelium, intense gagging, an inability to swallow, vomiting, retrosternal pain, and airway obstruction. Opioid therapy is effective in relieving pain but can lead to gastric stasis and intestinal pseudo-obstruction. Some regimens, notably those that contain cytarabine, etoposide, high-dose melphalan, or multiple alkylating agents, may cause unusually severe intestinal mucosal necrosis and further delay the return of eating. Oral cryotherapy has been shown to decrease the severity and duration of oral mucositis after high-dose melphalan [41]. Myeloablative conditioning therapy makes most patients nauseated and anorexic, leading to delayed gastric emptying [38] and poor oral intake, with a nadir at day 10–12 post-transplant but often extending to day 20 [42]. Conditioning therapy can lead to activation of vagal afferents by serotonin released from enterochromaffin cells [43]. Serotonin-antagonist drugs are very effective in relieving acute symptoms during conditioning therapy, with the second-generation 5-HT$_3$ receptor antagonist palonosetron also being helpful in treating delayed nausea and vomiting (day 2–5) [44,45]. Addition of dexamethasone and/or NK1 antagonists that block the action of substance P may prevent breakthrough nausea and vomiting [46]. Protracted anorexia may be related to circulating IL-1, IL-6, and tumor necrosis factor-alpha (TNF-α), cytokines known to affect appetite centers [42].

Upper gut GVHD

Early signs of acute GVHD include loss of appetite, absence of pleasure from eating, and satiety, often followed by nausea and vomiting, especially when more subtle signs are not investigated. When the onset of GVHD is before day 15, following a peripheral blood allograft, for example, the histologic features of GVHD may be indistinguishable from those resulting from conditioning therapy. Some patients never experience improvement in appetite before the onset of GVHD, but rather have a seamless persistence of anorexia and nausea. After day 20, over 80% of patients with intractable anorexia, nausea, or vomiting will have gastric and duodenal GVHD as the sole explanation [47]. Endoscopy shows edema of the gastric antral and duodenal mucosa, patchy erythema, and bilious gastric fluid [48]. Histology may show epithelial cell apoptosis and dropout, often with localized lymphocytic infiltrates [48,49]. However, the predictive value of negative histology for GVHD is not high, as what the endoscopist sees as mucosal edema is not what the pathologist relies upon to make a diagnosis of GVHD (apoptosis of crypt cells) [50]. Hence the gamut of clinical presentation, endoscopic appearance, absence of infection, and histology needs to be integrated to arrive at a diagnosis when histology is equivocal [48,49,51]. Immunosuppressive therapy using a 10-day induction course of prednisone 1 mg/kg/day plus oral beclomethasone dipropionate 8 mg/day is an effective therapy for upper gut-predominant GVHD that avoids prolonged prednisone exposure [52,53]. In patients whose symptoms have responded to this 10-day regimen, tapering prednisone over 1 week but continuing topical glucocorticoid therapy is adequate for most patients with upper gut GVHD. Recipients of autologous grafts may also develop a syndrome of anorexia, nausea, and vomiting that is associated with diffuse gastric edema and erythema [54]. Gastric histology shows typical GVHD, and symptoms respond to a 10-day course of prednisone 1 mg/kg/day.

Infection

Endoscopy also serves to rule out intestinal infection with herpesviruses, bacteria, and fungi. CMV infection of the esophagus and upper intestine accounted for one-third of patients with unexplained nausea and vomiting during the pre-ganciclovir era, but CMV infection is now an uncommon cause of these symptoms [47]. CMV infections in the gastrointestinal tract are usually diagnosed between 50 and 150 days after HCT [55], but can appear earlier if patients have CMV infection before HCT or receive cord blood transplants [3,56]. CMV infections can be detected in the gastrointestinal tract in the absence of CMV antigen or DNA in peripheral blood. HSV esophagitis may present in patients not receiving prophylactic acyclovir. Fungal esophagitis may cause anorexia but not the incessant vomiting often seen with GVHD or CMV infection. Nausea and vomiting may be prominent symptoms of some parasitic infection (if missed during pre-HCT screening) [9,10] and infections caused by non-culturable viruses (norovirus, rotavirus, astrovirus) [11]. Anorexia and vomiting may also be manifestations of increased intracranial pressure related to CNS infection; other neurologic signs and symptoms usually dominate the clinical picture with these disorders. Non-infectious causes of increased intracranial pressure may also present with nausea and vomiting, for example, cyclosporine-related pseudotumor cerebri and subdural hematomas.

Medications

Oral non-absorbable antibiotics (particularly nystatin), cyclosporine, mycophenolate mofetil (MMF), trimethoprim–sulfamethoxazole, voriconazole, posaconazole, itraconazole, intravenous amphotericin, and high-dose opioids also cause nausea and occasionally vomiting. Infusions of fat, glucose, and amino acids in total parenteral nutrition reduce appetite, slow gastric emptying, and cause nausea. Even after total parenteral nutrition has been stopped, appetite suppression may linger for 1–3 weeks [57].

Jaundice, hepatomegaly, and abnormal liver tests

Development of jaundice following HCT is an ominous prognostic sign, with increased non-relapse mortality in patients whose total serum bilirubin exceeds 4 mg/dL [58,59]. In patients with acute GVHD, jaundice is an independent predictor of mortality [60,61]. Because treatment of severe liver dysfunction is often futile, transplant physicians must recognize risk factors for hepatobiliary problems before the transplant process starts, implement measures to prevent liver damage, and identify post-transplant liver disorders that have specific treatments [1,59]. Over the last decade, this approach has resulted in a marked reduction in the incidence of liver injury and clinical jaundice, resulting from prevention of hepatic sinusoidal injury, fungal and viral prophylaxis, and the introduction of prophylactic ursodiol for all patients undergoing transplant [2]. Nonetheless, there remain multiple hepatic causes of jaundice and elevations of serum alanine aminotransferase (ALT) and alkaline phosphatase (ALP) [1,59]. Additional processes can contribute to jaundice following HCT while not usually being important causes of jaundice in isolation, for example, hemolysis and renal insufficiency.

Sinusoidal obstruction syndrome (SOS)

Definition

SOS is a syndrome of tender hepatomegaly, fluid retention and weight gain, and elevated serum bilirubin that follows some high-dose myeloablative conditioning regimens. This form of liver injury is initiated by damage to hepatic sinusoids; occlusion of hepatic venules is not essential to development of signs and symptoms, hence the older term “venocclusive disease” (VOD) is inaccurate.

Incidence

The frequency and severity of SOS have fallen dramatically because: (1) doses of total body irradiation (TBI) >14 Gy are seldom used; (2) fludarabine is replacing CY; (3) patients at risk for SOS are now given liver-friendly regimens that do not contain either CY or TBI >12 Gy; (4) the prevalence of chronic hepatitis C in transplant candidates, formerly a common risk factor for SOS, is now very low; and (5) therapeutic drug monitoring allows personalized dosing of chemotherapy drugs that have variable metabolism [1]. SOS is caused by toxins in certain conditioning regimens; important contributors to variability in the incidence of SOS are (1) variations in the metabolism of CY from patient to patient in CY/TBI regimens [62]; (2) underlying fibro-inflammatory liver diseases; (3) the order of delivery of drugs in multidrug conditioning regimens [63,64]; (4) concomitant use of drugs during and after conditioning therapy that either affect the metabolism of myeloablative drugs (e.g., itraconazole) or cause concomitant liver injury (e.g., methotrexate, sirolimus, norethisterone). Although fatal SOS has nearly disappeared from most adult transplant units [2,65], pediatric patients receiving busulfan/melphalan conditioning regimens remain at risk [66]. Many past patients diagnosed as having SOS on the basis of jaundice probably had mostly cholestatic and not sinusoidal liver injury, a conclusion based on data from ursodiol prophylaxis studies [2,67,68].

Clinical presentation and diagnosis

The onset of SOS is heralded by an increase in liver size, right upper quadrant tenderness, renal sodium retention, and weight gain, occurring 10–20 days after the start of CY and later after other myeloablative regimens [1]. Hyperbilirubinemia follows these signs of portal hypertension by 4–10 days. Concomitant renal and lung dysfunction and refractory thrombocytopenia strongly suggest SOS [69,70]. Measurement of total serum bilirubin is a sensitive test for SOS but not a specific one. Elevations of serum aspartate aminotransferases (AST/ALT) weeks after the clinical onset of SOS reflect ischemic hepatocyte necrosis from sinusoidal fibrosis [71]. Several plasma proteins have been reported to be abnormally high in patients with SOS (endothelial cell markers, thrombopoietin, proinflammatory cytokines, vascular endothelial growth factor, procollagen peptides and a panel of biomarkers); some laboratory tests are abnormally low in patients with SOS (protein C, antithrombin III, and platelet counts). These tests do not appear to have diagnostic or prognostic utility beyond the clinical criteria of weight gain, jaundice, and hepatomegaly. Doppler ultrasound is useful for demonstrating hepatomegaly, ascites, periportal edema, attenuated hepatic venous flow, and gall bladder wall edema consistent with SOS, in addition to excluding other causes of hepatomegaly and jaundice. Abnormal findings later in the course of SOS may include an enlarged portal vein diameter, slow or reversed flow in the portal vein or its segmental branches, high congestion index, portal vein thrombosis, and increased resistive index to hepatic artery flow. Unfortunately, ultrasound findings very early in the course of SOS – when there is often diagnostic uncertainty – do not appear to add to the information provided by clinical criteria.

A transvenous approach that allows both biopsy and hepatic venous pressure measurements is the most accurate diagnostic test. A hepatic venous pressure gradient above 10 mmHg is highly specific for SOS [72,73]. Initial histologic changes are dilation of sinusoids, extravasation of red cells through the space of Disse, necrosis of perivenular hepatocytes, and widening of the subendothelial zone in central veins [74,75]. A finding of “hemorrhage” in zones 2 and 3 of the liver acinus is the result of destruction of sinusoidal endothelium – the initiating injury in SOS. In severe SOS, fragmented hepatocyte cords can be seen, with dislodgement of hepatocytes into both portal and hepatic venules. The later stages of SOS are characterized by activation and proliferation of stellate cells, extensive collagenization of sinusoids, and a variable degree of obstruction of venular lumens leading to obliteration of sinusoidal blood flow [74,75]. In severe SOS – if patients survive beyond day 50 post-transplant – a pattern of reverse cirrhosis may develop, with extensive linkage between obliterated central venules by fibrous bridges, collapse, and acinar extinction. Intensity of collagenization of sinusoids and central veins and the degree of hepatocyte necrosis as reflected in serum ALT levels are correlated with outcome [71,75].

Clinical course and prognosis

Complete recovery from SOS occurs in over 70% of patients with just supportive care. Patients with severe SOS seldom die of liver failure, but rather from renal and cardiopulmonary failure [69,70]. For research purposes, a retrospective scoring system classifies SOS as mild (clinically obvious, requires no treatment, resolves completely), moderate (signs and symptoms requiring treatment such as diuretics or pain medications, resolves completely), or severe (requires treatment but does not resolve before death or day +100). Useful prognostic findings include the rapidity with which weight is gained and serum bilirubin rises, serum AST/ALT levels over 1500 U/L, development of ascites, renal insufficiency, and hypoxemia [69–71,76].

Pathogenesis of SOS (reviewed in [74,77])

Toxic damage to hepatic sinusoidal endothelial cells, not venular damage and not thrombosis within the liver vasculature, is the proximate cause of SOS. The most common causes of sinusoidal damage are regimens that contain CY and regimens that include TBI, with the combination of CY and TBI doses over 12 Gy being the most common cause of fatal SOS [69]. The metabolism of CY is highly variable and unpredictable; patients who generate a greater quantity of toxic CY metabolites are more likely to develop fatal SOS [62]. Accurate methods to target the dose of CY to a metabolic endpoint allow personalized CY dosing, significantly reducing liver and kidney injury [78]. These methods are not widely available, but data suggest that a total CY dose of 100–110 mg/kg, instead of 120 mg/kg, will lower the frequency of organ toxicity in the CY/TBI regimen [78]. In combination with CY 120 mg/kg, there is a clear relationship between the total dose of TBI and the frequency of severe SOS – approximately 1% after CY/TBI 10 Gy, 4–7% after CY/TBI 12–14 Gy, and 20% after CY/TBI >14 Gy. Busulfan (BU) is another component of regimens with a high frequency of SOS, but BU itself does not appear to be hepatotoxic [79,80]. BU may contribute to liver injury by inducing oxidative stress, reducing glutathione levels in hepatocytes and sinusoidal endothelial cells, and altering CY metabolism [64,79]. Giving CY before intravenous targeted BU, particularly in patients with myelofibrosis [29], leads to less liver toxicity than with targeted BU/CY or i.v. BU/CY [80a,64] [64]. Melphalan pharmacokinetics, also widely variable from patient to patient, can be normalized using therapeutic drug monitoring [81]. Gemtuzumab ozogamicin causes sinusoidal liver injury in about 10% of patients with acute myeloid leukemia (AML) [34]. The risk of SOS increases when high-dose gemtuzumab ozogamicin given in proximity to myeloablative regimens that contain sinusoidal toxins. Gemtuzumab may also cause SOS when given for relapsed AML after HCT.

Procollagen peptides appear in the serum of patients who develop more severe SOS, along with inhibitors of fibrolysis, consistent with the intense fibrosis in sinusoids and venular walls that is common in fatal SOS. Immunohistology for α-actin in liver specimens from patients with SOS shows intense staining in activated stellate cells, the source of collagen deposition into sinusoids [74].

Genetically determined differences in drug metabolism or susceptibility to toxic injury might explain some of the variability in the frequency of SOS, but there is no current method of altering drug dosing or determining the susceptibility of individual patients to sinusoidal injury based on genomic data [82].

Prevention of SOS in patients receiving myeloablative therapy

The only certain way to prevent fatal SOS is to avoid damaging hepatic sinusoidal endothelial cells, especially in patients at risk. The challenge for transplant oncologists is to remove drugs that are toxic to sinusoidal endothelial cells from conditioning regimens without sacrificing engraftment or malignancy relapse rates. Prevention of severe sinusoidal liver injury begins with an assessment of the risk in patients with underlying liver disease, for a given myeloablative conditioning regimen (Table 94.1). These strategies have had a striking effect on the frequency of SOS as a complication of HCT [2,65].

Patients at risk for fatal SOS have several options: (1) conventional therapy that does not involve HCT; (2) a reduced-intensity conditioning regimen; (3) a myeloablative regimen that does not contain CY, for example, targeted BU–fludarabine for allogeneic [83,84] or BEAM for autologous [85] HCT; (4) modification of CY-based regimens with either a change in the order (CY/targeted BU [64], for example) or reduction in CY dose to 100–110 mg/kg [78]; (5) use of pharmacologic approaches to prevent sinusoidal liver injury. Of the proposed methods for more accurate, personalized dosing of chemotherapy

Table 94.1 Factors that increase the risk of severe sinusoidal liver injury resulting from the conditioning regimen

Liver diseases at baseline	Specific conditioning regimens	Concomitant drugs during conditioning therapy
Inflammatory diseases	***Cyclophosphamide-based***	Itraconazole
Chronic hepatitis B or C	CY 120 mg/kg + TBI (greater risk with higher TBI dosing)	Sirolimus (rapamycin)
Non-alcoholic steatohepatitis	BCV (BCNU + CY + VP-16)	Norethisterone
Alcoholic hepatitis	BU + CY (greater risk without therapeutic drug monitoring of BU)	
Fibrotic diseases		
Cirrhosis	***Melphalan-based***	
Lobular fibrosis	BU + MEL + thioTEPA	
Myelofibrosis (extramedullary hematopoiesis with sinusoidal fibrosis)	BU + MEL	
Cholestatic disorders	***Other regimens***	
Jaundice caused by intrahepatic cholestasis	BU + TBI (greater risk with higher TBI dosing)	
Past history	Gemtuzumab ozogamicin-containing myeloablative regimens	
Prior SOS from conventional chemotherapy	High-dose radiolabeled antibody myeloablative regimens	
Recent exposure to gemtuzumab ozogamicin		
Prior liver irradiation		
Prior myeloablative hematopoietic cell transplant		

BCNU, bis(chloroethyl)nitrosourea; BU, busulfan; CY, cyclophosphamide; MEL, melphalan; thioTEPA, *N*-triethylenethiophosphoramide; TBI, total body irradiation.

agents, only therapeutic drug monitoring has been studied in the HCT setting [78,86]. If a CY/TBI regimen must be used for a patient at risk for fatal SOS, modifications should be considered for both CY (100–110 mg/kg) and TBI (≤12 Gy) dosing. Shielding the liver during TBI will lessen liver injury but leads to relapse of underlying hematologic disease. If a BU/CY regimen must be used for a patient at risk for fatal SOS, liver toxicity is less frequent if CY is given before targeted BU [64] or if dosing of CY is delayed for 1–2 days after completion of BU. The metabolism of intravenous BU is variable, with a several-fold range in AUC_{BU}, a problem that can be addressed by therapeutic drug monitoring [84]. Use of therapeutic drug monitoring to normalize exposure to melphalan is also feasible [81]. Another approach to decreasing the toxicity of regimens that contain BU and melphalan is to give them in reverse order (MEL/BU).

Pharmaceutical prevention of SOS has been achieved in animal models of sinusoidal injury, but these strategies (repletion of intracellular GSH or inhibition of matrix metalloproteinase enzymes) have not been studied in the clinical setting. Infusion of defibrotide has been reported to be effective as prophylaxis; results from a large randomized trial in children reported less liver disease and marginally better outcomes in those receiving defibrotide [66]. Prospective studies have shown no benefit from the use of prophylactic heparin, antithrombin III, or *N*-acetylcysteine in preventing fatal SOS. A meta-analysis suggested that ursodiol may prevent SOS [68], but SOS was not differentiated from cholestatic liver disease in these studies and a large randomized trial showed no effect of ursodiol on the frequency of SOS but a large effect on the frequency of cholestatic jaundice [67].

Treatment of patients with SOS

For >70% of patients with SOS who will recover spontaneously, treatment involves management of sodium and water balance, preservation of renal blood flow, and repeated paracenteses for ascites that is associated with discomfort or pulmonary compromise. Patients with a poor prognosis can be recognized soon after disease onset by steep rises in total serum bilirubin and body weight, serum ALT values >1500 U/L, portal pressures over 20 mmHg, development of portal vein thrombosis, and especially by multiorgan failure requiring dialysis, hemofiltration, or mechanical ventilation [69–71,76]. There are no satisfactory therapies for severe SOS; the best current results (46% complete response rate, defined as total serum bilirubin <2 mg/dL and resolution of multiorgan failure) are with intravenous defibrotide [87]. Defibrotide, a mixture of porcine oligodeoxyribonucleotides, has antithrombotic and profibrinolytic effects in vitro and in vivo. However, its mechanism of action in the treatment of SOS is not known. The complete recovery of some patients with severe SOS and multiorgan failure suggests that the drug has biologic effects in man; defibrotide appears to be safe when given after HCT [88]. There have been no randomized trials.

Numerous other approaches to the treatment of severe SOS have been reported (tissue plasminogen activator, intravenous *N*-acetylcysteine, human antithrombin III concentrate, activated protein C, prostaglandin E_1, prednisone, topical nitrate, vitamin E plus glutamine, and use of a liver assist device), but none can be currently recommended. Transhepatic shunts have been placed in patients with SOS to reduce portal pressure and mobilize ascites, but neither serum bilirubin levels nor patient outcomes were improved. Patients with persistent ascites and normal serum bilirubin have undergone successful portosystemic shunts. Peritoneovenous shunts for intractable ascites have been unsuccessful. Successful liver transplants for severe SOS have been reported [89]. However, in most centers, patients at risk for recurrent malignancy are low-priority candidates for a cadaveric liver. Prevention of sinusoidal injury has proven to be a more effective strategy for improving transplant outcomes than treatment of patients with severe sinusoidal damage [2].

Cholestatic disorders: cholangitis lenta, acute GVHD, and drug-induced liver injury

Prophylactic ursodeoxycholic acid reduces the frequency of cholestasis in general and GVHD-related cholestasis specifically and improves outcomes, compared with placebo [2,67]. Now that the frequency of SOS has declined greatly, the leading cause of post-HCT jaundice is cholestatic liver injury [1,59].

Cholangitis lenta

Hyperbilirubinemia is common when patients are neutropenic and febrile and have gut mucosal injury from the conditioning regimen. Hepatocyte retention of conjugated bilirubin is mediated by endotoxins, IL-6, and TNF-α [90]. Although this disorder is often referred to as "cholestasis of sepsis," it occurs in patients with fever alone and in the presence of localized infection in the lungs and soft tissues.

Acute GVHD

Acute GVHD develops in up to 70% of allograft recipients. Prophylaxis with ursodiol has greatly decreased the frequency of jaundice after transplant and has altered the clinical phenotype of GVHD [2,67]. In retrospect, what had been called hepatic GVHD is a mélange of three processes. The first process is jaundice developing in a patient with cutaneous and intestinal GVHD. A blinded study could identify no histologic features characteristic of GVHD when liver biopsies were performed within several weeks of the onset of GVHD [91], suggesting that jaundice occurring early in GVHD is related to cholestasis caused by cytokines such as IL-6 [42]. The second process is characterized by increases in bilirubin, AP, and γ-glutamyl transferase (GGT), usually in patients with gastrointestinal GVHD, in whom liver biopsies show lymphocytic infiltration of small bile ducts with nuclear pleomorphism, epithelial cell dropout, and cholestasis in zone 3 of the liver acinus [91]. Although the bile duct lesions of GVHD resemble those of primary biliary cirrhosis and some patients have positive antimitochondrial antibodies (AMAs), all AMA-positive samples are false positives and the histology differs (no granulomata or large bile duct lesions are seen in GVHD) [92]. Inflammatory infiltrates may be minimal because of immune suppression. Persistent hepatic GVHD and worsening jaundice are associated with ductopenia. The third process in hepatic GVHD is most commonly seen in allograft recipients on minimal immunosuppression or after donor lymphocyte infusion, in whom GVHD presents as an acute hepatitis with marked elevation of serum ALT [93,94]. Prognosis in patients with GVHD is not related to peak severity of signs and symptoms, but rather to the area under a disease activity curve where persistent jaundice is an independent predictor of mortality [60]. Although anecdotal evidence suggests that some immune suppressive regimens result in resolution of cholestatic liver injury more frequently that with other regimens, data from controlled trials are lacking, for example, pulse CY [95] or extracorporeal photopheresis or switching from one calcineurin inhibitor (CNI) to another or sirolimus or oral budesonide.

Drug-induced liver injury

Cyclosporine inhibits canalicular bile transport and commonly causes mild increases in serum bilirubin without an effect on serum ALT or AP. Tacrolimus less commonly causes cholestasis, except in the setting of toxic blood levels. Many other drugs used after HCT have been associated with liver dysfunction (e.g. trimethoprim–sulfamethoxazole, itraconazole, voriconazole, fluconazole, posaconazole), although drugs are usually not responsible for severe liver injury in this setting [33,71].

Acute hepatitis

The incidence of severe hepatocellular injury after HCT has declined remarkably from the 1990s to the current time, most likely due to declining incidence of severe SOS [2,71]. A sudden rise in serum aminotransferase enzymes (AST and ALT) following HCT is usually due to a non-infective cause such as zone 3 hepatocyte necrosis in SOS (peaking around day 20), hypoxic liver injury (as in septic or cardiac shock or respiratory failure), acute biliary obstruction (choledocholithiasis), drug-induced liver injury, or the acute hepatitic presentation of GVHD [1]. If a likely cause is not apparent, acute viral hepatitis should be suspected; early diagnosis and treatment may prevent a fatal outcome.

Acute hepatitis caused by HSV, varicella zoster virus (VZV), adenovirus, and HBV can lead to fatal fulminant hepatic failure after HCT, whereas hepatic infections caused by CMV and HCV are seldom severe. With routine use of prophylactic acyclovir/valacyclovir, acute hepatitis due to HSV and VZV is now rare; however, human herpesvirus-6 (HHV-6) and HHV-8 reactivation and hepatitis E virus (HEV) as causes of hepatitis have been reported after HCT [96,97]. When there is uncertainty about the cause of rising serum ALT and AST levels, serum PCR tests for herpesviruses, adenovirus, HCV, HBV, and, in some circumstances, HEV should be performed. Blood tests for viruses have largely replaced the need to obtain liver tissue for viral diagnosis, but transvenous measurement of the wedged hepatic venous pressure gradient and transvenous liver biopsy can be useful in the diagnosis of unsuspected SOS or another cause of hepatiocyte necrosis. If acyclovir is not being given, it should be started empirically, particularly if the patient presents with abdominal complaints typical of VZV infection [98]. Adenovirus hepatitis should be suspected if the patient has concomitant pulmonary, renal, bladder, or intestinal symptoms but may present just with fevers, raised liver enzymes, and hypodense regions in the liver on abdominal CT scan along with features of bone marrow suppression [99]; the most effective treatment is cidofovir when given early in the course of infection, but many cases are fatal [100,101]. New agents are in development.

Fulminant hepatitis B may develop during immune reconstitution in patients at risk, but can be prevented with prophylactic antiviral agents [102]. If severe hepatitis B reactivation does occur, usually because a diagnosis of HBV was not made prior to HCT, antiviral therapy with the most potent antiviral drug available (entecavir or tenofovir) should be initiated immediately; however, progression to fatal liver failure is not uncommon [103]. Fulminant hepatitis B has also been reported following discontinuation of prophylactic antiviral therapy, and all patients, particularly those with high pre-transplant HBV DNA levels, should be monitored following antiviral drug withdrawal [104,105].

Chronic hepatitis C in HCT recipients usually results in asymptomatic elevation of ALT from days 60 to 120, coinciding with the tapering of immunosuppressive drugs [25]. DAA therapy after HCT should be considered for patients with fibrosing cholestatic hepatitis C [26]; those with cirrhosis whose condition is deteriorating [28]; and patients who underwent HCT for HCV-related lymphoproliferative disorders [105a]. HCT recipients are characteristically receiving multiple drugs that could have substantial pharmacologic interactions with DAAs (including, but not limited to, cyclophosphamide, etoposide, tacrolimus, cyclosporine, sirolimus, posaconazole, and voriconazole) [105b, 105c, 105d, 105e]. Future DAA regimens are likely to be pangenotypic, of short duration and well tolerated without significant drug drug interactions. Therapy directed at chronic HCV infection should be considered once the patient has ceased all immunosuppressive drugs and has no evidence of active GVHD [106], as discussed in the later section Problems in long-term transplant survivors.

Fungal and bacterial infections

Antifungal prophylaxis has significantly reduced the incidence of hepatic fungal disease in HCT recipients, particularly in those requiring ongoing immunosuppression for treatment of GVHD [107]. If invasive fungal disease involving the liver does occur, presenting features include fever, tender hepatomegaly, and increased serum AP levels; resistant *Candida* species or molds should be suspected [107]. High-resolution CT scan or MRI may demonstrate multiple fungal abscesses, and serologic tests for fungal antigens may be useful for diagnosis [35]. Treatment courses may need to be protracted in immunosuppressed patients with visceral fungal infection, but return of neutrophil function after HCT can effect resolution of previously treatment-refractory *Aspergillus* infection [108]. Bacterial liver abscesses are rare in HCT recipients, probably because systemic antibiotics are so widely used; however, latent mycobacterial infection may reactivate within the liver with prolonged immunosuppressive therapy. Disseminated Bacille Calmette–Guérin infection with liver involvement has been reported. Disseminated clostridial infection and gall bladder infection with gas-producing organisms may lead to air in the liver and biliary system.

Gall bladder and biliary disease

Biliary sludge (calcium bilirubinate and crystals of CNIs) is very common in HCT recipients [109]. Biliary sludge is usually asymptomatic; however, passage down the bile duct may cause epigastric pain, nausea, and abnormal serum liver enzymes. Biliary sludge may be a cause of acute "acalculous" cholecystitis, acute pancreatitis, and bacterial cholangitis [110,111]. Acute cholecystitis is uncommonly seen in HCT recipients and is frequently without larger gallstones [112]. Cholecystitis in this setting may also be due to leukemic relapse with gall bladder involvement or infection by CMV, fungi, or rarely by other organisms such as *Hemophilus influenzae*. GVHD may affect gallbladder mucosa.

Diagnosis of cholecystitis after HCT is difficult because of the high frequency of gall bladder abnormalities on ultrasound or CT in asymptomatic patients. Pericholecystic fluid, gall bladder wall necrosis or localized tenderness suggest cholecystitis. Non-visualization of the gall bladder after a radionuclide bile excretion study with morphine infusion suggests cholecystitis. Biliary obstruction is a rare event, caused by a variety of disorders [e.g., common bile duct calculi or inspissated biliary sludge; GVHD of the ampullary mucosa; lymphoblastic infiltration of the common bile duct, gall bladder, and ampulla of Vater in Epstein–Barr virus (EBV) lymphoproliferative disease; CMV-related biliary disease; dissecting duodenal hematoma complicating endoscopic biopsy; and leukemic relapse (chloroma) in the head of the pancreas] [111,112]. In patients undergoing autologous transplantation, biliary strictures are commonly due to recurrent malignancy [113]. Non-invasive imaging (ultrasound, magnetic resonance cholangiopancreatography, CT cholangiography) or endoscopic ultrasound is usually adequate to demonstrate biliary pathology. Use of ursodiol as a stimulant of bile flow in patients with biliary sludge after HCT is ineffective. Endoscopic retrograde cholangiopancreatography is indicated only in patients with clinical evidence of cholangitis and radiologic evidence of biliary obstruction and allows for biliary stenting or dilatation with acceptable risk [112,113].

Malignant disorders

EBV lymphoproliferative disease is now an infrequent complication of HCT, largely because of EBV DNA surveillance and preemptive treatment with rituximab. The highest incidence is in recipients of HLA-mismatched, T-cell-depleted grafts and those receiving potent anti-T-cell therapies for GVHD. Symptoms include fever, sweats, generalized malaise, enlarged tonsils, and cervical lymphadenopathy, often with liver involvement (abnormal serum ALP and hepatosplenomegaly) and gastrointestinal invasion. Recurrent cancer in patients transplanted for leukemia, lymphoma, or solid tumors may present with abnormal liver enzymes, hepatomegaly, or abnormal imaging studies within the first year after HCT.

Idiopathic hyperammonemia and coma

A syndrome of hyperammonemia and coma has been described in patients who received high-dose chemotherapy, including conditioning for HCT [114]. Patients present with progressive lethargy, confusion, weakness, incoordination, vomiting, and hyperventilation with respiratory alkalosis. The diagnosis is confirmed when the plasma ammonia exceeds 200 μmol/L and there is no evidence of liver failure. This syndrome is rare, but is associated with high mortality. Its pathogenesis likely involves the unmasking of a latent genetic disorder similar to ornithine transcarbamylase deficiency in children [115]. If available, urinary metabolic screen should be performed.

Gastrointestinal bleeding

Bleeding that does not require transfusion is very common, particularly when platelet counts are below 50×10^9/L. Causes include retching trauma to esophageal or gastric mucosa, mucosal injury from conditioning therapy, peptic esophagitis, *C. difficile* colitis, anal fissures, internal hemorrhoids, and acute GVHD. The incidence of severe gastrointestinal bleeding after HCT is 1–2% – lower than in the past because of effective prophylaxis against viruses, fungi, and acute GVHD [116]. Mortality from severe intestinal bleeding, however, remains at 40% [116,117].

The most common cause of severe bleeding is refractory acute GVHD, with bleeding from extensive ulceration in the small intestine and cecum. In some patients with GVHD, bleeding may appear to be coming from specific areas of the mucosa, but when such patients are operated on or come to autopsy, diffuse rather than focal mucosal ulceration is the rule [118]. Bleeding is an independent predictor of mortality in patients with severe gut GVHD [61]. Ulcers in the stomach or duodenum that develop after HCT are usually caused by acute GVHD or CMV infection, but with ganciclovir prophylaxis and preemptive therapy, bleeding CMV ulcers have become rare [116]. Gastric ulcerations may also be caused by infection by VZV, bacteria (phlegmonous gastritis) or EBV (lymphoproliferative disease). Although now rare after HCT, EBV lymphoproliferative disorder involves the gastrointestinal tract in 20–25% of cases and can present as gastrointestinal bleeding. Gastric antral vascular ectasia is also a cause of severe upper intestinal bleeding in HCT recipients, particularly those who have received oral BU [119]. Diffuse areas of hemorrhage are seen in the gastric antrum and occasionally small and large intestine, but the underlying mucosa is intact [119–121]. Histology is diagnostic, revealing abnormal dilated capillaries, thromboses, and fibromuscular hyperplasia in the lamina propria. Patients who are transplanted for advanced systemic sclerosis may bleed from similar vascular lesions. Endoscopic laser therapy and argon plasma coagulation are treatments of choice to control bleeding from vascular ectasia, but multiple treatments may be required to obliterate ectatic lesions [119]. Other rare causes of bleeding post-HCT include ulcers caused by molds, yeasts, Dieulafoy lesions, Curling (stress) ulcers, duodenal biopsy sites, mycophenolate-induced enteritis, adenovirus enterocolitis, and *C. septicum* infection (typhlitis). Patients with severe amyloidosis who undergo autologous HCT may bleed from multiple ischemic ulcers throughout the intestine [122].

There is no effective therapy for mucosa that is diffusely oozing blood other than raising the platelet count to $>50 \times 10^9$/L and treating the underlying condition. Continuous infusion of octreotide at 25 μg/hour has resulted in cessation of bleeding from GVHD, but recurrent bleeding developed when infusion was decreased [123]. In GVHD, re-epithelialization of ulcerated intestinal mucosa is very slow. Focal lesions, especially mucosal infection, can be treated with endoscopic cautery, heater probe, or epinephrine injection provided that platelet counts are adequate, but these therapies are futile in mucosa that is oozing blood diffusely. Unless the underlying disease process is eliminated, endoscopic methods will not cure the bleeding problem. Attempts to resect large segments of diffusely bleeding intestine involved with GVHD have not been successful [118].

Dysphagia, painful swallowing, and esophageal pain

Oral and hypopharyngeal mucositis, acid–peptic esophagitis, and pill esophagitis are currently the leading causes of dysphagia and esophageal pain. Infections of the esophagus (fungal, viral, bacterial) have largely disappeared because of antimicrobial prophylaxis; when fungal esophagitis is discovered in a patient receiving fluconazole, the organism is likely to be a resistant candidal species or a mold [124]. Rarely, fungal esophagitis can lead to perforation [125].

Mucositis caused by conditioning therapy may lead to pain on initiating a swallow and inability to move a bolus past the cricopharyngeus, symptoms that can also be seen with oropharyngeal GVHD or HSV infection. Rarely, non-healing esophageal ulcerations, strictures, and dysphagia result from conditioning therapy [126]. In patients with gastric stasis related to acute GVHD, painful esophagitis is common, caused by reflux of both gastric acid and bilious fluid. The use of proton pump inhibitor therapy, although effective in treating acid–peptic reflux, may lead to colonization of the aerodigestive system with bacteria and fungi, and increased risk of *C. difficile*-associated colitis [127,128]. Symptom relief can be obtained by treating the cause of gastric stasis and placing the patient in the reverse Trendelenburg position when in bed. The abrupt onset of severe retrosternal pain, hematemesis, and painful swallowing suggests a hematoma in the wall of the esophagus, a result of retching when platelet counts are very low [129]. Endoscopy is relatively contraindicated, as many intramural hematomas represent contained perforations. CT is the diagnostic test of choice [130]. The course of intramural hematomas is one of slow resolution over 1–2 weeks. In patients with severe GVHD, esophageal edema, erythema, and a peeling epithelium lead to ulcerations [131]. Pill esophagitis occurs after ingestion of some medications that might be used after HCT, for example phenytoin (dilantin), foscarnet, captopril, oral bisphosphonates, ascorbic acid, ciprofloxacin, clindamycin, and oral potassium chloride. Most cases resolve within a few days without specific therapy beyond discontinuance of the offending medication.

Diarrhea

Conditioning therapy

Diarrhea caused by mucosal damage from conditioning therapy is seldom severe, usually resolving by day 12–15, with some exceptions. Cytarabine-containing regimens, high-dose melphalan (≥ 200 mg/m^2), and regimens containing multiple alkylating agents may cause more severe, protracted diarrhea. Intravenous infusion of octreotide and oral loperamide (at 4 mg orally every 6 hours) may be effective for severe diarrhea associated with conditioning therapy [132]. There is a correlation between the amount of diarrhea in the week following completion of conditioning therapy, serum levels of TNF-α and IL-6, and the risk of subsequent GVHD [133,134].

GVHD

Acute GVHD is the most common cause of diarrhea after day 15 [135]. However, GVHD may not be the sole cause of diarrhea in an individual patient, especially in patients receiving prolonged immune suppression, in whom restaging the cause of diarrhea may detect infections not present at baseline [136]. The onset of GVHD diarrhea can be sudden, with volumes in excess of 2 L daily in severe cases. GVHD in patients who were grafted after reduced-intensity conditioning regimens may have its presentation delayed, occurring after day 100 in many patients [137]. The diarrheal fluid of GVHD is watery, green in color, with ropy strands of mucoid material that reflect transmucosal protein loss. In an allografted patient with skin and liver abnormalities typical of acute GVHD, this diarrheal syndrome is almost diagnostic of intestinal GVHD, particularly when accompanied by decreasing serum albumin and negative stool studies for infection [138]. In atypical cases where GVHD is suspected, abdominal imaging with CT may reveal intestinal edema and mucosal enhancement, particularly in the ileum and right colon, although the appearances of acute GVHD and CMV infection overlap [139,140]. Ultrasound can also demonstrate bowel wall thickening and hypervascularity; contrast-enhanced ultrasound may provide sufficient specificity for diagnosis of GVHD [141,142]. Similar information can be obtained with positron emission tomography (PET) imaging. Pneumatosis intestinalis, which may be associated with GVHD or CMV enteritis, may be seen by plain X-ray, CT, or MRI, and in the absence of ancillary evidence of clinical severity, managed conservatively [143].

A definitive diagnosis of GVHD in problematic cases requires endoscopic views of mucosa, histology of mucosal tissue, and exclusion of infection. What the endoscopist sees should carry equal diagnostic weight to what the pathologist sees through the microscope [48]. In mild cases, gastroduodenal and rectosigmoid mucosa are grossly normal, but moderately severe GVHD causes diffusely edematous and erythematous mucosa throughout the gastrointestinal tract. Severe GVHD may lead to ulcerations and large areas of mucosal sloughing in the stomach, small intestine, and colon [144]. Even when the appearance is normal, biopsies from the gastric antrum or rectosigmoid colon often reveal intestinal crypt necrosis and apoptotic bodies diagnostic of acute GVHD [145]. The diagnostic yield of mucosal biopsy is best when biopsies are obtained either from the stomach and distal colon or from the colon and ileum [135,144,145]. Reports by endoscopist and pathologist can be discordant, as mucosal edema and erythema are not criteria that are used for the histologic diagnosis of GVHD; visual inspection of the mucosa should be viewed as complementary to histologic findings. Other histologic findings that support the diagnosis of GVHD include pericapillary hemorrhage, infiltrating neutrophils or eosinophils, and evidence of endothelial damage. The use of capsule endoscopy for diagnosis of GVHD has been described; this method does not allow biopsy, but can provide visual inspection of the small intestine that cannot be seen with routine endoscopy [146]. The predictive value of a negative capsule endoscopy examination of the small intestine appears to be high, and therefore useful for excluding more severe acute GVHD.

In severe cases of GVHD, whole crypts are destroyed, then adjacent crypts, and finally whole segments of intestinal mucosa. Bleeding often accompanies diarrhea in patients with mucosal ulceration [116]. Successful treatment of acute GVHD with immunosuppressive therapy results in a dramatic reduction in stool volume, with resolution of accompanying symptoms of abdominal pain, nausea, and vomiting. The management of patients whose diarrhea and other symptoms of intestinal GVHD persist after 5 days of immunosuppressive therapy is unsatisfactory, as the rate of failure of secondary therapy is high [147]. Mortality in patients with high-volume diarrhea caused by GVHD can be predicted by a panel of clinical features within 14 days of onset: jaundice, age over 18 years, lack of response to prednisone, and gastrointestinal bleeding [61]. Other methods of predicting outcome in patients with GVHD include calculation of the Acute GVHD Activity Index, fecal calprotectin level, GVHD Risk Score measurement of decline of serum albumin from baseline, and panels of serum biomarkers [60,138,148,149a,b,c]. Plasma biomarkers that appear to be useful in predicting more severe GVHD and non-relapse mortality include TIM3, sTNFR1, ST2, Reg3a, IL6, and angiogenic factors [149d, 149e, 149f, 149g, 149h]. It is not clear whether early predictors of mortality in patients with severe GVHD have any utility in preventing death in the absence of curative therapy.

Infection

In allograft recipients, infectious causes of diarrhea are far less common than GVHD, accounting for only 10–15% of diarrheal episodes [117,135,150]. Common bacterial pathogens are extremely rare after HCT [150]. except in geographic areas where such infections are prevalent [7]. There are several infections that can closely mimic intestinal GVHD or, more commonly, coexist with GVHD, including non-culturable enteric viruses (norovirus, rotavirus, astrovirus), mycobacteria, fungi, and parasites [124]. *C. difficile* colitis is usually a relatively mild, treatable disease when diagnosed at the onset of diarrhea [135,151]. The recent emergence of more virulent strains of *C. difficile* has changed the natural history of this infection, and prevention of nosocomial *C. difficile* infection in both hospital and outpatient settings has therefore become even more important. One often overlooked factor is the inappropriate use of proton-pump inhibitors for marginal indications, which increases the risk of *C. difficile* colitis twofold [128]. The most common cause of infectious diarrhea in one prospective study was astrovirus (a small, round virus similar to norovirus); diagnosis can be made by PCR of stool specimens or by electron microscopy of small intestinal biopsies [135,152]. Norovirus may also spread within hospitals as a nosocomial infection in HCT patients, with devastating consequences [11]. Some serotypes of adenovirus cause necrotizing enteritis and rapidly fatal multiorgan failure involving the gut, liver, lungs, and kidneys [124,153]. There should be a sense of urgency in identifying adenovirus as a cause of enteritis, as delayed treatment is often ineffective [154,155]. However, not all patients in whom adenovirus is found in diarrheal stools have adenovirus enteritis.

CMV is the only common infectious cause of enteritis after HCT that requires an intestinal biopsy for diagnosis [135]. As with adenovirus, CMV DNA can be detected in diarrheal stool specimens from patients who do not have demonstrable mucosal CMV disease. CMV can be found in mucosal biopsies in patients whose blood is negative for CMV antigen or DNA [3,156]. Otherwise, the predictive value of a negative stool examination for other viruses, bacteria, fungi, and parasites is high, particularly if molecular methods are used [157]. After HCT, watery diarrhea secondary to intestinal parasite infection (*Cryptosporidium*, *Giardia lamblia*, *Entamoeba histolytica*, helminths) is rare among patients who come to transplant without diarrhea, but sporadic cases are seen that can be confused with GVHD [9,10,158]. *Strongyloides* infection and hyperinfection syndrome have been described after HCT; patients from endemic areas should be screened before HCT [159]. Non-tuberculous mycobacterial infection of the small intestine has been described post-HCT [160,161].

Other causes of diarrhea

In addition to infection, several other conditions may mimic GVHD or may contribute to diarrhea that might otherwise be attributed to GVHD, for example, brush border disaccharidase deficiency, bile salt malabsorption, pancreatic insufficiency, mucosal toxicity from MMF, and intestinal thrombotic microangiopathy (Table 94.2).

Intestinal inflammation often results in downregulation of brush border disaccharidases such as lactase and sucrase/isomaltase, leading to diarrhea if lactose or sucrose is ingested. Failure of bile salt absorption in the small intestine leads to inefficient water transport in the colon, a mechanism of diarrhea in patients with gut GVHD that can be treated with bile acid sequestrants such as colesevelam [162]. Pancreatitis and pancreatic insufficiency have been associated with CNI therapy [163]. Transient pancreatic insufficiency has been described as a consequence of mucosal edema at the ampulla of Vater [164]. Japanese investigators have described intestinal microangiopathy related to CNIs as a disorder that mimics GVHD [165]. MMF causes intestinal ulcerations and apoptotic crypt cells indistinguishable from the histology of acute GVHD [166]. In a patient with intestinal symptoms whose immunosuppressive drug regimen includes MMF, it may be difficult to make a diagnosis of GVHD until MMF has been discontinued. Fewer gastrointestinal side effects have been reported after conversion to enteric-coated mycophenolic acid in solid organ transplant recipients [167]. Diarrhea may also result from carbohydrate malabsorption (particularly in patients on antibiotics that affect the colon flora's ability to salvage carbohydrate), oral magnesium salts, tacrolimus (a motilin agonist), plerixafor (an immunostimulant) and brincidofovir (an oral antiviral drug). The multiple causes of diarrhea not directly caused by GVHD in an allograft recipient may explain why diarrhea is not a component of the Acute GVHD Activity Index that predicts day 200 non-relapse mortality [60]. A syndrome of antibiotic-responsive, culture-negative diarrhea has been reported in cord blood recipients with *Bradyrhizobium enterica* as a futative cause. Pathology of endoscopic biopsies shows chronic active colitis with granulomas, and patients have responded to antibiotics, albeit with a high recurrence rate [168]. This syndrome has not been found in other transplant centers [168a].

Table 94.2 Difficult-to-diagnose disorders that can mimic or complicate gastrointestinal acute GVHD

Disorder	Comments
Mycophenolate mofetil toxicity	A wide range of gastrointestinal pathology has been described in MMF-treated organ transplant patients. Very difficult to differentiate from GVHD in the setting of HCT. Far less gut toxicity is seen with enteric-coated mycophenolic acid
Cytomegalovirus or adenovirus infection	Diagnosis may be difficult when virus in present only in gastrointestinal mucosa (blood can be virus free). Differentiating infection from gut mucosal disease can be difficult
Brincidofovir toxicity	Diarrhea caused by gut mucosal damage is a dose-limiting toxicity of this anti-viral drug.
Cryptosporidial infection	Rare and treatable only by withdrawing immunosuppression. Molecular diagnosis (PCR) is far more accurate than microscopic methods of diagnosis
Non-culturable virus infections (astrovirus, norovirus, rotavirus)	The most common post-HCT infection(s) in a prospective study, but seldom diagnosed because of lack of commercial diagnostic tests. PCR is now widely available for diagnosis of norovirus infection
Tacrolimus-related thrombotic microangiography	The hypothesis is that tacrolimus-related vascular injury leads to ischemic damage to mucosa. Withdrawal of tacrolimus has been followed by improvement in some cases
Non-tuberculous mycobacterial infections	Granulomatous mucosal involvement is part of the spectrum of mycobacterial infections in transplant patients
Diffuse fungal infection	Mold infection leading to granulomatous enteritis has been described
Osmotic diarrhea related to carbohydrate malabsorption	Lactose, sucrose, isomaltose in the diet may cause diarrhea if gut inflammation has led to downregulation of brush-border disaccharidases. Antibiotics that depress anaerobic colon flora will impact the ability of anaerobes to metabolize malabsorbed carbohydrate
Bile acid malabsorption	Bile acids not retrieved in the ileum will inhibit salt and water transport in the colon. Potentially treatable with colesevelam but at the risk of binding oral medications

Abdominal pain

It is extremely important to distinguish abdominal pain as an indicator of a rapidly progressive, fatal illness from illnesses with a benign natural history that require only conservative management. The illnesses that may be rapidly fatal include intestinal perforation, some infections (e.g. typhlitis caused by *C. septicum*, adenovirus enteritis, visceral VZV infection, *Aspergillus* vasculitis), gall bladder necrosis, and bacterial liver abscess. Fortunately, these disorders are far less common than intestinal pseudo-obstruction (dilation of the bowel in the absence of a mechanical obstruction), narcotic bowel syndrome (non-propulsive segmental contractions), acute GVHD, liver pain related to SOS, and hemorrhagic cystitis – causes of severe pain to be sure, but not imminent death. A systematic approach in evaluating abdominal pain in these difficult patients is important in excluding rapidly fatal diseases.

Does the patient need urgent surgery?

Surgical intervention for pain after HCT is a rare event, but is indicated for intestinal perforation, acute cholecystitis, drainage of abscesses, appendicitis, and in some patients with intestinal or biliary obstruction, typhlitis, and dissecting hematomas [169]. Deciding who has one of these conditions as a cause of pain and who does not depends mostly on the clinical situation, abdominal examination, and judicious use of imaging. Modern imaging tests (ultrasound, MRI, and CT scan) and careful examination should allow the surgeon to be highly selective in choosing candidates for operation, Clinical judgment may lead to surgical exploration or laparoscopy in problematic cases when one cannot exclude the possibility of a surgical disease, for example, pneumoperitoneum of unknown cause or possible gall bladder necrosis. Intestinal perforation may develop in the setting of lysis of a transmural lymphoma or metastatic carcinoma shortly after conditioning therapy, or later from CMV ulcers or diverticular perforation. Perforation may present with only mild-to-moderate abdominal pain and pneumoperitoneum on abdominal CT, especially in granulocytopenic patients. Pneumoperitoneum can also be a manifestation of pneumatosis intestinalis, a much more benign process than free perforation, usually caused by CMV or GVHD [170]. Recognition of acute cholecystitis is more difficult, as right upper quadrant pain (usually from SOS) and fever are common in the early post-HCT period, and imaging studies frequently show gall bladder wall thickening and luminal sludge in completely asymptomatic patients. A radionuclide study with morphine that shows filling of the gall bladder suggests that surgical cholecystitis is not present, but false-positive results (i.e. lack of gall bladder filling) do occur in severely ill patients on total parenteral nutrition [171]. The diagnosis of SOS as a cause of pain can usually be resolved by its timing of onset in relation to conditioning therapy, by liver tenderness on examination, and by consistent findings on Doppler ultrasound [1]. When pain is localized to the right lower quadrant, typhlitis (*C. septicum* infection) and appendicitis are diagnoses that can be made by imaging, along with exclusion of other causes of right lower quadrant pain (renal, ovarian, abdominal wall). The most common cause of moderate-to-severe abdominal pain, intestinal pseudo-obstruction with bowel distention, does not usually require abdominal imaging, as the finding of distention and tympany on percussion in the setting of opioid or anticholinergic drug exposure is virtually diagnostic. Most patients with pseudo-obstruction have an underlying intestinal disease, such as enteritis from conditioning therapy, GVHD, or infection. Pseudo-obstruction is more frequent among patients transplanted for lymphoma or myeloma, as a result of intestinal neuropathy from past use of vincristine. In visceral VZV infection, abdominal distention, severe pain, fever, and rising serum ALT levels may precede cutaneous manifestations by up to 10 days – a presentation that occurs only among patients not receiving acyclovir prophylaxis [98,172]. Acyclovir should be started on clinical suspicion while serum is analyzed by PCR for VZV DNA. Clinical pancreatitis is an uncommon cause of abdominal pain in HCT patients; subclinical pancreatitis does occur, with symptoms masked by immunosuppressive drugs [110]. Patients with low platelet counts or prolongation of blood clotting may rarely bleed into the retroperitoneum, abdominal wall, or intra-abdominal viscera, particularly after duodenal biopsy, causing significant pain.

Is the pain a manifestation of acute GVHD?

Acute gastrointestinal GVHD can present with just abdominal pain, but more commonly, a skin rash, nausea, vomiting, anorexia, or diarrhea accompany pain. GVHD causes pain by two mechanisms: gut wall edema and distention with malabsorbed fluid. The presentation can include a rigid abdomen with rebound tenderness, but more commonly crampy and periumbilical pain are present. With gastric mucosal edema, pain is localized to the epigastrium. The decision to treat a patient empirically when definitive evidence of GVHD is not at hand is difficult, but when the pretest probability of GVHD is high and that of perforation or infection low, prednisone therapy at 2 mg/kg/day should be started. CT abdominal imaging or abdominal ultrasound (particularly with sonographic contrast) shows intestinal wall thickening in acute GVHD, a non-specific but highly suggestive finding, particularly when CMV infection is unlikely [139,141,173]. Although one might withhold prednisone therapy until a definitive biopsy diagnosis has been made, delays in therapy may lead to more extensive mucosal necrosis and morbidity. If the pain later proves to be due to causes other than GVHD, prednisone can be discontinued.

Is the pain due to a treatable infection?

Recent advances in antiviral and antifungal prophylaxis have made intestinal and liver infections rare causes of abdominal pain [2]. Disseminated VZV may present with difficult-to-explain abdominal pain 2–6 months after HCT in someone not currently receiving acyclovir or ganciclovir therapy. Importantly, abdominal pain may precede typical VZV skin lesions by several days [98]. Marked hyponatremia due to the syndrome of inappropriate antidiuretic hormone secretion and elevated serum ALT (from VZV hepatitis) have also been observed in this setting [174]. Patients should be started on intravenous acyclovir while a definitive diagnosis is sought (VZV DNA in serum, gastric mucosal or liver biopsy). Pain from visceral VZV infection may be poorly localized, and the patient may not look particularly unwell at presentation, but if not treated promptly, the disease can follow a rapidly fatal course. Other intestinal infections that may present with significant pain include adenovirus, CMV, cryptosporidia, invasive molds such as *Rhizopus*, *C. difficile* colitis, and *C. septicum* cecitis (typhlitis). Symptoms of typhlitis include fever, right lower quadrant pain, nausea and vomiting, diarrhea, occult blood in the stool, and shock; the diagnosis of typhlitis is usually made by imaging studies showing cecal edema [175]. Surgical resection for typhlitis is rarely necessary provided that imipenem and oral vancomycin therapy for *C. septicum* are started along with systemic coverage for luminal bacteria and fungi in febrile patients [176].

Is the pain caused by intestinal pseudo-obstruction?

In patients with intestinal pseudo-obstruction and gaseous distention, medical management is almost always effective and perforation rare. Although there are some infections of gut neurons (VZV and CMV) that lead to pseudo-obstruction, opioid and anticholinergic medications are the usual causes, particularly in patients with gut inflammation. There are three approaches to opioid-related pseudo-obstruction: (1) decreasing the opioid dose to low levels; (2) peripheral μ-opioid receptor blockade with methylnaltrexone [177]; or (3) switching to a κ-opioid agonist (e.g., butorphanol).

Anticholinergic medications are contraindicated in this setting, and drugs with anticholinergic side effects should be discontinued. In patients who are on a respirator, gaseous distention can be prevented by use of a nasoesophageal sump tube connected to suction, thus eliminating swallowed air from entering the gut. Neostigmine (2 mg intravenously) has been successfully used in patients with acute colonic pseudo-obstruction after HCT [178]. If gut distention and pain are caused by fluid, as in severe acute GVHD, or by true obstruction, a rare event, the approach is to place a nasogastric or nasoenteric sump tube to prevent further accumulation, and then address the underlying cause. Octreotide is useful for treating gut distention with fluid related to obstruction.

Identification of other causes of abdominal pain

Once the diseases that need urgent surgical or medical care have been ruled out, one can perform directed diagnostic tests to identify specific causes of pain. Cystitis is usually seen after CY exposure but also occurs with adenovirus or polyomavirus infection; it is always accompanied by hematuria. Hematomas of the abdominal wall or intestine should be suspected in patients with a rapidly expanding anterior abdominal wall mass or obstructive symptoms after intestinal biopsy in the setting of profound thrombocytopenia.

Perianal pain

Perianal pain after HCT can be caused by an anal fissure, a thrombosed external hemorrhoid, cellulitis related to tissue maceration, and infections. In patients with granulocytopenia, infections in the perineum or perianal spaces are usually polymicrobial, arising either from anal glands or from tears in the anal canal. After HCT, these infections can be difficult to recognize because they may not produce abscesses but rather a spreading cellulitis. Extensive supralevator and intersphincteric abscesses may be present without being apparent on external examination [17]. CT or MRI scans or endoscopic or transperineal ultrasound can give a clear view of the anatomy involved, particularly if there is pus present [179]. When antibiotics covering both anaerobic and aerobic bacteria are given to patients with "cryptitis" (incipient perianal infection), far fewer patients require surgical drainage than in the past [18]. Rarely, surgical drainage will be needed for patients with abscesses and rapidly progressive tissue necrosis. Unusual causes of perianal pain include giant condyloma acuminata (genital warts) caused by human papillomavirus, HSV infection, fungal infection, and CMV-induced cutaneous vasculopathy with perineal ulcers [19,180].

Problems in long-term transplant survivors

Gastrointestinal and hepatobiliary problems in the second year after allogeneic HCT are usually a continuation of symptoms of protracted acute GVHD, chronic graft-versus-host disease (cGVHD), medication side effects, and infection related to immune suppression [1,37,181]. As time passes, as tolerance develops, and as immunity improves, the frequency and severity of these problems wane – but new problems involving the gut and liver may arise, sometimes decades later.

Gastrointestinal problems

Esophageal symptoms: heartburn, dysphagia, and painful swallowing

Heartburn may be worse if cGVHD is present because salivary gland destruction reduces bicarbonate production, which normally neutralizes refluxed gastric acid. cGVHD may also involve the esophagus, leading to dysmotility and failure to clear refluxed acid [182]. Protracted acute GVHD involving the stomach leads to gastric stasis and reflux of both bile and acid. To minimize esophageal injury, patients should elevate the head of their bed by 4–6 inches, avoid all protein intake within 4 hours of bedtime, and take a proton pump inhibitor. Less common causes of esophagitis in survivors include fungal and viral infection and inflammation caused by retained pills (pill esophagitis). There is a long list of pills that cause esophageal injury, including non-steroidal anti-inflammatory drugs (NSAIDs) and oral bisphosphonates. Pill esophagitis presents with dysphagia and painful swallowing, and can lead to perforation and difficult-to-dilate strictures if offending pills are continued.

Dysphagia can be a particularly difficult symptom; common causes include esophageal and oral cGVHD, infection, xerostomia, and poor dentition [181]. Tongue and hypopharyngeal inflammation can make initiating a swallow difficult. Myasthenia gravis, a rare complication of cGVHD, is an extreme example of hypopharyngeal dysmotility [183]. Patients with extensive cGVHD often complain of dysphagia, for solid food and pills. Some patients, especially children, present with insidious weight loss, retrosternal pain, and aspiration of gastric contents, leading to pulmonary disease that can be mistaken for GVHD-related bronchiolitis obliterans syndromes. The diagnosis of esophageal cGVHD is made by barium contrast X-ray and endoscopy, which should be done with caution, as perforations have been reported. Radiologic findings include bullae, webs, concentric rings, narrowings, strictures, and aperistalsis [181]. Sloughed mucosa may hang in shreds into the lumen, visible to the radiologist as a web or a fibrous shelf at the level of the cricopharyngeus. Long, tapering strictures in the proximal and midesophagus are better seen by X-ray than by endoscopy. Endosopic findings include bullae, desquamation of the epithelium, upper esophageal webs, ring-like narrowings, and tapering strictures [181]. Histologic findings include infiltration of the esophageal mucosa with lymphocytes, neutrophils and eosinophils, necrosis of individual squamous cells in the basal layer, and desquamation of the superficial epithelium. Patients with esophageal cGVHD need systemic immunosuppressive therapy. However, even when the inflammatory component is under control, submucosal esophageal fibrosis may lead to abnormal peristalsis, luminal narrowing, and persistent symptoms. Esophageal strictures and webs may require endoscopic dilation to avoid progressive luminal narrowing, but dilations must be performed with extreme care, as the perforation risk is higher than with peptic strictures. Failure to dilate strictures may lead to progressive esophageal narrowing and require a feeding gastrostomy. A fibrotic, stenotic esophagus that cannot be dilated may require esophagectomy and interposition surgery. Topical glucocorticoid therapy can be effective for esophageal inflammation [184,185]. The risk of squamous cell carcinoma of the esophagus is 10-fold higher after HCT than among controls; cGVHD is the major risk factor [186].

Upper gut symptoms: anorexia, nausea, vomiting, satiety

Gastroduodenal GVHD in long-term survivors does not fall under the heading "chronic GVHD" but rather "protracted acute GVHD" because symptoms, endoscopic appearance, and histology are identical whether they occur before day 100 or years after transplant [181]. Gastrointestinal symptoms of protracted acute GVHD can appear in the absence of cGVHD elsewhere. Long-term use of oral topical glucocorticoid can be effective in patients with protracted upper gut GVHD [187,188]. However, both prednisone and topical glucocorticoids can lead to suppression of the hypothalamic–pituitary–adrenal axis, particularly in children, and symptoms of adrenal insufficiency (anorexia, nausea) may mimic those of upper gut GVHD. Now rare, a syndrome of diarrhea, abdominal distention, and severe malabsorption has been described in patients with untreated cGVHD who had extensive submucosal and subserosal fibrosis [181]. Focal intestinal strictures, however, can be seen as sequellae of gut GVHD.

Herpesviruses (HSV, CMV, VZV) may cause nausea, vomiting, and satiety in survivors who have not fully reconstituted immunity, especially if prophylactic antiviral medications and viral surveillance have been discontinued. When upper gut symptoms appear along with abdominal distention and elevated serum ALT levels, visceral VZV infection should be at the top of the list of possible diagnoses; the test of choice is PCR for VZV DNA in blood [124]. Gut infection with enteric viruses (e.g. rotavirus and norovirus) and parasites (*Giardia lamblia*, cryptosporidia) can present with anorexia and nausea with minimal diarrhea [10]. In areas where *Helicobacter pylori* is prevalent, it may be difficult to discern the cause of upper gut symptoms when both infection and GVHD are present [189].

Mid-gut and colonic symptoms: diarrhea and abdominal pain

Protracted acute GVHD can cause gastrointestinal inflammation decades after transplant, with symptoms that wax and wane. Diarrheal symptoms usually respond to opioids but can require a short course of immune suppressive medications or topical glucocorticoids. Histologic findings are similar to those of microscopic enterocolitis (lymphocytic inflammation with occasional apoptotic crypt cells) [49]. Some patients who have had more severe GVHD in the past present later with enigmatic abdominal pain, often with a history that suggests intestinal obstruction (pain in the interdigestive period, distention, relief with diarrheal stools). Some will have an identifiable area of obstruction or inflammation on CT enterography, MRI, barium contrast, or capsule endoscopy, but in others, no discrete abnormality can be found [190]. This presentation can also be seen with narcotic bowel syndrome, in patients who still require opioids for pain. Vague abdominal symptoms may be a manifestation of colon or ovarian cancer, particularly in patients over 50 years old.

Sporadic cases of gut infection may occur (*C. difficile*, norovirus, CMV, and rarely *Giardia* and cryptosporidia) [124]. Rarely, chronic intestinal viral infection can be seen in patients who remain on immunosuppressive drugs, for example, rotavirus, norovirus, and adenovirus. These infections may mimic GVHD [10]. MMF may cause gastrointestinal toxicity, usually manifest as diarrhea and colon ulcerations, with apoptotic crypt cells indistinguishable from the histology of GVHD [166]. In a patient with intestinal symptoms whose immunosuppressive drug regimen includes MMF, it may be difficult to make a diagnosis of GVHD until MMF has been discontinued or changed to enteric coated mycophenolic acid [167]. Bile acid malabsorption in the ileum, leading to inhibition of salt and water resorption in the colon, may contribute to persistent lower volume diarrhea; bile acid-sequestering agents such as colesevelam may be helpful [162]. Rare cases of "transmission" of intestinal disease via donor T cells have been reported, for example, inflammatory bowel disease and celiac sprue [191].

Liver diseases

GVHD

There are three presentations of liver GVHD in long-term survivors [1,37,181]: (1) Asymptomatic elevation of serum ALT, AP, and GGT as isolated laboratory abnormalities, in the absence of jaundice; (2) slowly progressive cholestatic jaundice, usually associated with elevated serum AP, a result of damage to small bile ducts; (3) acute hepatocellular injury (hepatitic GVHD), that is, abrupt elevations of serum ALT to over 500 U/L without preceding hepatic dysfunction. Hepatitic GVHD tends to occur especially in the setting of tapering immunosuppressive therapy or after donor lymphocyte infusion [93,94]. Diagnosis of liver GVHD may require a liver biopsy, particularly in patients who develop hyperbilirubinemia. Patients with jaundice secondary to destruction of small bile ducts by GVHD or those with an acute hepatitic presentation of GVHD may die if there is delay in starting immunosuppressive therapy.

In long-term survivors, the differential diagnosis of jaundice is narrower than it is before day 100, and there is an imperative for immediate treatment according to cause. The differential diagnosis of cholestatic jaundice includes GVHD, biliary obstruction, drug-induced liver injury (DILI), and fibrosing cholestatic hepatitis B or C [1]. Iron overload has been reported to mimic mild GVHD [192]. In contrast, patients with asymptomatic elevations of serum ALT, AP, and GGT may have subclinical liver GVHD, DILI, ethanol effect, biliary disease, infiltrative liver disease, or inflammation related to fat accumulation (non-alcoholic steatohepatitis). If a cause of elevated liver enzymes is not apparent, a biopsy may be indicated to identify GVHD as a cause. While elevated ALT, AP, and GGT may presage destructive damage to small bile ducts and ductules, immunosuppressive therapy (and thus liver biopsy) are not usually indicated when stable, minor elevation of serum enzymes is the only finding. The addition of ursodiol (12–15 mg/kg/day) to the immunosuppressive regimen results in significant biochemical improvement in liver GVHD [193]. The long-term use of ursodiol is safe and well tolerated and should be prescribed for survivors with cholestatic liver injury, along with standard immune suppressive drugs used to treat cGVHD [194].

A major issue is how best to treat survivors whose liver GVHD has not responded to standard therapies. Avoiding precipitous decreases in immune suppression and recognizing laboratory signs of impending destruction of small bile ducts caused by GVHD should prevent deep, prolonged jaundice in most. However, some patients reach the point of ductopenia and deep jaundice because of discontinuation of immune suppression to achieve a graft-versus-leukemia (GVL) effect, or because of donor lymphocyte infusion (DLI). Hepatologists have long recognized that recovery from small bile duct injury is highly variable, even when the cause is a drug that can be discontinued, and GVHD is no exception to this variability in outcomes. Some patients whose total serum bilirubin levels over 25 mg/dL have reverted to normal over the course of several months of therapy with prednisone, CNI, and ursodiol therapy [93], but in most such cases, prednisone-sparing immune suppression is sought because of glucocorticoid side effects and infection risk. Several case series, but no randomized trials, have touted as effective treatments pulse cyclophosphamide [95] or extracorporeal photopheresis or switching from one CNI to another or sirolimus. Oral beclomethasone dipropionate or budesonide could be used for hepatic cGVHD, as ~30% of these topical glucocorticoids reach the portal circulation [195] and the liver; this approach to other inflammatory liver diseases has been effective. Liver transplantation, including living-donor transplantation from the original hematopoietic cell donor, has been performed patients with refractory cholestasis or end-stage liver disease due to GVHD [89,196–198].

Patients who present with an acute hepatitis, that is, steeply rising serum ALT with or without jaundice, present a differential diagnosis of viral infection, DILI, and hepatitic GVHD. These patients require urgent diagnosis and treatment. Hepatic histology is usually needed to confirm the diagnosis of GVHD; histological findings include hepatocellular injury, lobular inflammation, lymphocytic infiltration in and around small bile ducts, extensive damage to, and loss of, small bile duct epithelial cells, cholestasis, portal fibrosis, and piecemeal necrosis [93]. A serum autoantibody test for CYP1A2 may prove useful in the diagnosis of hepatic GVHD, as this enzyme appears to be a target antigen in GVHD [199]. Blood tests for viral antigen or DNA/RNA will exclude acute hepatitis due to a herpesvirus (HSV or VZV), a hepatitis virus (hepatitis A–E), or adenovirus. Acyclovir should be started pending results of tests for herpesviruses; if viral studies are negative, a CNI and prednisone 1–2 mg/kg/day should be begun while histology is pending to prevent extensive ductular damage from GVHD [93].

Chronic viral hepatitis and cirrhosis

HCV infection in HCT survivors almost always results in chronic hepatitis. In the first 10 years of HCV infection after HCT, there is little liver-related morbidity except for rare cases of fibrosing cholestatic hepatitis [27]. However, cirrhosis of the liver related to chronic HCV infection is rising in frequency among patients transplanted before the 1990s. In a cohort of 195 HCV-infected HCT recipients followed prospectively, the cumulative incidence by 20 years of severe liver complications, including cirrhosis, liver failure, and liver transplantation, was 11.7% [200]. The rate of progression of HCV is higher in HCT recipients than in matched controls, with reports of cirrhosis in up to 24% by 20 years of follow-up and 35% after 40 years [201]. The reasons for more rapid fibrosis progression after HCT are unclear, but may be related to concomitant liver involvement with GVHD, iron overload [202], and immunosuppression. Clues to the presence of cirrhosis include a switch in the normal ratio of serum aminotransferases so that AST is higher than ALT, thrombocytopenia, and hepatic nodularity and splenomegaly on imaging, although thrombocytopenia may be unrelated to liver disease in HCT survivors. Confirmation of cirrhosis using either liver biopsy or non-invasive methods such as transient elastography [30] is crucial so that antiviral treatment can be prioritized and patients can be monitored for complications including esophageal varices and hepatocellular carcinoma. Chronic hepatitis C may also be a risk factor for development of lymphoma and other lymphoproliferative disorders after transplant [105a,203,204].

All patients with chronic HCV, including those with compensated cirrhosis, should be considered for DAA antiviral therapy unless contraindications exist. Therapeutics for HCV treatment are rapidly evolving; we recommend consulting with a hepatologist or infectious disease specialist and this website for continuously updated information on genotype-specific drugs of choice: http://www.hcvguidelines.org. Future DAA regimens are likely to be pangenotypic, of shorter duration, and without significant drug-drug interactions. Liver transplantation should be considered in any HCT survivor with hepatic decompensation or early hepatocellular carcinoma. Living-donor transplantation from the original stem-cell donor is an attractive consideration in this situation, as minimal immunosuppression would likely be required in the long term [196,205].

The prevalence of chronic HBV infection among HCT survivors varies widely depending on the country. The serologic pattern of HBV infection may be atypical in HCT survivors, probably as a consequence of immunosuppression. Clearance of surface antigenemia may be observed, and is particularly likely if the donor was anti-HBs positive because of prior HBV infection [22]. Patients who remain HBsAg positive after HCT are at risk of flares of hepatitis activity, particularly at times of reduction of immunosuppression, such as during taper or cessation of treatment for chronic GVHD, and there should be a low threshold for having these patients on oral antiviral agents such as tenofovir or entecavir. All long-term survivors with chronic hepatitis B should be regularly monitored to assess virologic and disease status, and the need for antiviral therapy. Hepatitis B DNA levels and liver enzymes should be monitored every 6–12 months regardless of whether the patient is on antiviral treatment. International guidelines should be followed with regard to making decisions about antiviral treatment [206–208]. The need for antiviral treatment with an oral nucleoside or nucleotide analog (such as entecavir or tenofovir) is based on the ALT and HBV DNA levels and the severity of hepatic fibrosis [209], and may change over time, hence the need continually to reassess patients who are not on treatment. Although pegylated interferon is used as first-line therapy in non-transplant patients with chronic HBV, it cannot be recommended in allogeneic HCT recipients because of the concern for flares of cGVHD. Non-invasive assessments of hepatic fibrosis using methods such as transient elastography are proving very useful in monitoring patients with chronic hepatitis B and making treatment decisions [210]. Long-term survivors with chronic hepatitis B do not seem to have an increased rate of progression to cirrhosis compared with non-HCT patients, and effective antiviral treatment should essentially prevent any disease progression. As HCT survivors are at increased risk of second malignancy or recurrent malignancy, care should be taken to reassess HBV viral status prior to reintroduction of chemotherapy [33]. Biologic agents, such as rituximab used in the treatment of B-cell malignancy, have a particularly high risk of reactivation of occult hepatitis B (HBsAg negative and anti-HBc positive), and prophylactic antiviral therapy is recommended. As in the peri-transplant period, patients with positive HBsAg should receive an antiviral agent whenever they receive immunosuppressive or cytotoxic therapy [211].

It is now recognized that HEV may result in chronic infection in immunosuppressed individuals, including HCT recipients. In contrast to water-borne HEV due to genotype 1 and 2 found in the developing world, HEV genotype 3 (HEV3) is found in mammalian reservoirs including domestic pigs, wild boar, and deer in Europe, North America, and China [96]. Infection from ingestion of undercooked meat from HEV3-infected animals may result in acute or chronic hepatitis, and reactivation may occur after HCT [97]. Diagnosis is by detection of anti-HEV antibodies and HEV RNA. Oral ribavirin has been shown to be effective therapy.

Ascites

The most common cause of new ascites in HCT survivors is cirrhosis, either the progression of cirrhosis present before transplant or a result of accelerated development of cirrhosis in patients with chronic hepatitis C [200,201,212] and rarely in patients with hepatic GVHD [198]. There are other, non-cirrhotic causes of enigmatic ascites: constrictive pericarditis, nodular regenerative hyperplasia, pancreatic ascites, peritoneal carcinomatosis, and a serositis syndrome related to cGVHD. The differentiation between intrahepatic sinusoidal hypertension and peritoneal causes of ascites is best made by the combination of the serum-ascites albumin gradient (SAAG) and cytology (to detect malignant cells).

Drug-induced liver injury

DILI may be related to antihypertensive drugs, lipid-lowering agents, hypoglycemic agents, NSAIDs, antidepressants, antibiotics, antifungal agents, or herbal preparations that are prescribed for the complications of HCT [33]. Some drug reactions result in chronic liver disease.

Acute hepatocellular injury

The differential diagnosis of extreme elevations of serum ALT in an HCT survivor includes acute viral hepatitis (including VZV hepatitis), a hepatitic presentation of chronic GVHD, flares of chronic hepatitis B or C, and drug-induced liver injury [1].

Hepatic iron overload

Iron overload may be an important cofactor in liver disease in long-term survivors, but cardiac, endocrine, and cancer-related effects of iron excess often outweigh the clinical impact of excess hepatic iron, as discussed below [37]. Iron overload is rarely, if ever, the sole cause of serious liver disease in HCT survivors. Iron overload is particularly severe in thalassemic patients who have undergone HCT [202]. Iron overload may rarely be a cause of liver enzyme elevation after HCT that responds to iron mobilization [192].

Hepatocellular carcinoma

Compared with the general population, patients who survive over 10 years post-HCT have an eightfold risk of developing a new solid malignancy. Because of the increased rate of chronic viral hepatitis, mostly hepatitis C, the risk of hepatocellular carcinoma is particularly elevated. Transplant survivors with risk factors for hepatocellular carcinoma (HCV cirrhosis, chronic HBV infection, or cirrhosis of any cause) should undergo surveillance with 6-monthly liver ultrasound scans according to international guidelines [213].

Nodular regenerative hyperplasia

Rarely, patients who receive high-dose chemotherapy in either the oncology or HCT setting will develop hepatic nodules (not separated by fibrosis) that compress portal venules [214]. This process is usually clinically silent unless ascites and esophageal varices develop; liver tests are normal. The diagnosis can be challenging, as both liver imaging and wedged hepatic venous pressure measurements can be misleadingly normal. A transjugular intrahepatic portosystemic shunt may be required for management of complications [215].

Focal nodular hyperplasia

In one series of HCT survivors undergoing liver MRI, incidental focal nodular hyperplasia (FNH) lesions were present in 12% [216]. The likely cause is sinusoidal injury caused by myeloablative conditioning regimens. FNH lesions have characteristic central scars that differentiate them from hepatocellular carcinoma and fungal lesions. Because their appearance is so characteristic on MRI [217], liver biopsy is often not necessary. However, when serum α-fetoprotein levels are elevated in patients with FNH, biopsy may be needed to exclude a hepatocellular carcinoma.

Fungal and bacterial infections

These liver infections are now rare late complications. Fungal or mycobacterial infection in the immediate aftermath of HCT can become quiescent, only to flare when exposed to prednisone. Nonsterile herbal remedies contaminated by molds and ingested may also lead to liver abscesses in survivors [218].

Gallbladder and biliary diseases

Long-term survivors have an increased incidence of gallstones and gallstone complications related to the formation of calcium bilirubinate microliths (biliary sludge) following myeloablative conditioning therapy [109]. These microliths serve as nucleating material for development of gallstones whose subsequent accretions are mostly cholesterol, yielding mixed pigment–cholesterol stones. Biliary sludge, gallstones, and crystals of CNI medications may cause cystic duct obstruction, common bile duct obstruction, and acute pancreatitis [111].

Pancreatic disease

Acute pancreatitis is very uncommon in long-term survivors, with most cases related either to biliary stone passage or, rarely, to tacrolimus-related pancreatic damage [219]. Pancreatic insufficiency has been noted in a small number of transplant survivors, usually diagnosed because of steatorrhea and weight loss despite adequate caloric intake. The etiology of pancreatic atrophy after HCT is not known; speculation centers around repeated subclinical episodes of pancreatitis, toxicity from drugs (prednisone, tacrolimus), stone or sludge passage, glandular destruction by GVHD, and infection by viruses with tropism for the pancreas [220,221]. Fat malabsorption caused by pancreatic insufficiency is diagnosed by a finding excessive fat in stool sample with a qualitative Sudan stain plus a dramatic response to pancreatic replacement therapy. Useful screening tests include measurement of serum trypsinogen (levels <20 ng/mL) and measurement of fecal elastase-1 and chymotrypsin. Pancreatic atrophy is detected by CT or MRI imaging [181,221]. Oral pancreatic enzymes are the only treatment for pancreatic insufficiency unless the cause is duct obstruction in the head of the pancreas.

Systemic iron overload

Secondary iron overload is caused by both repeated transfusions and increased gastrointestinal iron absorption in the setting of ineffective erythropoiesis and inflammatory conditions, including GVHD. Morbidity from iron overload in transplant survivors comes mostly from cardiac iron accumulation, which is only marginally correlated with liver iron content [222].Serum ferritin is commonly used as an indirect measure of body iron stores, but specificity is problematic as serum ferritin can be elevated in a variety of infectious and inflammatory states [36]. Iron-specific MRI methods can accurately measure not only liver iron, but also iron accumulation in the heart, pituitary, pancreas, and thyroid [223].

The effects of persistent iron overload on long-term HCT outcomes have not been fully investigated except in patients transplanted for thalassemia, in whom very high iron burdens translate to increased mortality from cardiac causes. However, recent studies suggest that iron overload could be a risk factor for increased non-relapse mortality among HCT survivors with less extreme iron burdens than in thalassemia patients [37]. Patients who died before day 100 after allogeneic HCT had levels of liver iron in the hemochromatosis range (1832–13,120 μg/g dry weight) [224]. The fate of excessive iron stores after successful HCT has been studied using serum ferritin, showing that serum ferritin levels fall slowly over time, reaching normal levels five or more years after HCT; the greater the iron loading at transplant, the longer it takes for normalization of serum ferritin [225,226]. In heavily iron-overloaded survivors, iron reduction therapy may significantly improve transplantation outcomes [227] and cardiac function, but few data are available for transplant survivors from underlying diseases other than thalassemia major.

Potential clinical consequences of iron overload in transplant survivors include cardiac, endocrine, and neurological disorders and development of secondary malignancy [37]. The risk of fatal cardiac ischemia, cardiomyopathy, and arrhythmias in HCT survivors is increased 3.6-fold over controls [228]. Although these late cardiac complications have been attributed to anthracycline therapy, myeloablative doses of cyclophosphamide, and chest radiation, elevated cardiac iron may play a role, as suggested by epidemiologic data from non-transplant patients with iron overload. In one study, some patients continued to accumulate cardiac iron despite a negative liver iron balance, suggesting that heart iron accumulation and cardiac dysfunction can occur despite good control of liver iron. Below a myocardial T2* of 20 ms, a progressive and significant decline in left ventricular ejection fraction has been noted. Data on cardiac iron loading in candidates for HCT and transplant survivors are limited. A study of 11 extensively transfused patients with myelodysplastic syndrome showed only one patient with T2* myocardial iron excess; this patient was without cardiac dysfunction [229]. Among 48 patients with early-stage hematologic malignancy, 85% had hepatic iron overload at the time of HCT (median 3100 μg/g dry weight), while only one patient had cardiac iron overload, defined as cardiac T2* <20 ms [230]. One study of 16 HCT survivors with liver iron concentrations of >5000 μg/g dry weight reported only one patient with cardiac dysfunction [231]. These results suggest that while significant hepatic iron overload is common in patients with hematologic malignancy before and after HCT, cardiac iron overload might be quantitatively less in contrast to patients with thalassemia major. At what point HCT survivors with liver iron excess develop cardiac iron deposition, at what point cardiac dysfunction develops after iron deposition, and the natural history of cardiac iron excess after transplant recovery are unknown.

Iron as a cancer-promoting factor has long been suggested on the basis of epidemiologic studies in both the population at large and in patients with genetic hemochromatosis [37]. The role of iron as a risk factor for cancer may not require iron excess, as two studies suggest that even in patients with iron levels in the normal range, iron mobilization may result in a lower incidence of cancer [232,233]. An increased risk (1.85–34-fold) of secondary malignancy in HCT survivors has been well documented and the cumulative incidence continues to increase over time [234,235]. No data are available on iron overload in long-term HCT survivors as a risk factor for secondary solid malignancy. If such a correlation exists, there is opportunity for cancer prevention through mobilization of iron stores.

Endocrine dysfunction can result from iron deposition in the anterior pituitary, pancreas, and thyroid; in patients with extreme iron overload such as thalassemia, these abnormalities may cause significant clinical effects [37]. Whether similar effects are related to iron excess in transplant survivors has not been studied.
